Anti-CD52 Monoclonal Antibody (Alemtuzumab)

Anti-CD52 mAb (alemtuzumab) is a humanized rat IgG2b directed against the CD52 antigen, which is expressed on 95% of peripheral blood lymphocytes, NK cells, macrophages, and thymocytes[27]; thus almost all mononuclear cells are affected. The profound and long-lasting lymphopenia produced after the administration of one or two doses of alemtuzumab is likely explained by such abundance on monocyte cell surfaces. Examination of the peripheral blood lymphocytes from recipients after alemtuzumab induction has identified a subset of T cells, predominantly CD4 central memory cells that survive despite alemtuzumab induction and appear largely resistant to depletion; these memory T cells express lower CD52 levels compared with naïve T cells.[28,29] CD52 is not present on granulocytes, platelets, erythrocytes, or hematopoietic stem cells (HSCs).

After binding to CD52, alemtuzumab causes cell death through several mechanisms: complement-mediated cytolysis, antibody-mediated cytotoxicity, and apoptosis. The plasma elimination half-life is approximately 12 days, whereas its clinical effects are far more persistent. Lymphocyte depletion of >99% can be seen after a single dose, with lymph node depletion taking up to 3–5 days compared with <1 hour seen in the peripheral lymphocytes. Different subpopulations display varying rates of recovery, depending on the subpopulation of interest: NK cells are almost unaffected and decrease only transiently (a population of $CD52^-$ NK cells has also been identified); monocyte and B-cell recovery can be seen at 3 and 12 months, respectively; T cells levels recover to only 50% of baseline at 36 months.[30]

Alemtuzumab is currently being used for induction in SOT with the aim of minimizing maintenance immunosuppression. It was first used in transplantation as an induction agent in 1998,[31] in 13 renal transplant recipients who received low-dose cyclosporine alone as maintenance therapy. At 6–12 months follow-up, patient and graft survival were 100%, and there were two episodes of acute rejection. The 5-year results of the initial series,[32] together with another 20 patients who were subsequently enrolled, showed no significant difference in graft or patient survival or in acute rejection rates compared with a retrospective, contemporaneous control group of 66 renal transplant recipients who had received no induction, but triple immunosuppression therapy alone (cyclosporine, azathioprine, and prednisolone). The study did also find, however, more episodes of late rejection in the alemtuzumab-treated group. Indeed, severe lymphopenia and homeostatic cytokines are known to drive the rapid homeostatic proliferation of naïve and memory T cells, and lymphocytes generated under such conditions have been previously found to be potent alloreactive cells, inevitably triggering rejection in animal models.[33] Investigation of this phenomenon in human recipients[28] illustrated that the recovery of the immune system after alemtuzumab induction differed with respect to CD4 and CD8 T cells. CD8 T cells recovered to pretransplantation levels by 6 months after alemtuzumab induction, whereas the number of CD4 T cells remained low, even at 1-year after transplantation. Repopulating CD8 T cells were mainly of the immunosenescent $CD28^-CD8^+$ phenotype, and the percentage of this population was lower in those recipients who experienced rejection compared with those who did not mount an immune response to their allograft. A series of *in vitro* experiments demonstrated that the expanded $CD28^-CD8^+$ T cells compete for immune space with CD4 T cells, suppressing their proliferation and thus delaying CD4 T-cell recovery. This delay might be associated with the clinical outcome because CD4 T cells, notably CD4 T effector memory cells, have been shown to be associated with rejection.[34]

Despite considerable experience with this agent over many years, largely in renal transplantation, until recently few randomized controlled trials had been conducted. Two randomized controlled clinical trials, the INTAC and 3C studies, investigating alemtuzumab induction in renal transplantation have now provided further insight.[35,36] The data from these studies support the use of alemtuzumab as an induction agent in low-risk patients, and the incidence of biopsy-confirmed acute rejection at 1 year was lower in patients treated with alemtuzumab compared with those treated with basiliximab induction. Similar to ATG, alemtuzumab cannot be used as a solitary immunosuppressive therapy and requires long-term maintenance immunosuppression to prevent allograft rejection. Importantly, in the 3C study, alemtuzumab induction therapy was found to result in reduced CNI and mycophenolate exposure and steroid avoidance, reducing the risk of biopsy-proven acute rejection in a broad range of patients receiving a kidney transplant, and this supported earlier data from smaller studies, including a study in lung transplant recipients.[37] However, patients with preformed DSAs despite a negative cross-match are at high risk of adverse outcomes when receiving a minimal immunosuppressive regimen incorporating alemtuzumab induction; these patients may thus benefit from augmented immunosuppression.[38]

Review of rejection episodes that have occurred with alemtuzumab induction, particularly in the absence of CNIs, has highlighted some interesting findings. Several authors have reported that a number of these rejections demonstrate positive staining for the complement component C4d, indicative of acute ABMR. In contrast, in acute rejection, examination of biopsy specimens taken from patients who had received both alemtuzumab induction and tacrolimus revealed none that was humoral in origin.[27] These data suggest that tacrolimus may prevent this early ABMR. Immune profiles of renal transplant recipients receiving alemtuzumab induction, 60 days of a CNI, and subsequent sirolimus monotherapy displayed a general increase in the naïve B-cell population.[39] Bloom et al. subsequently showed that B cell–activating factor (BAFF), a B-cell survival cytokine influencing the threshold of B-cell activation, substantially increased in renal transplantation following treatment with alemtuzumab.[40] This observation may help explain and prevalent the development of alloantibody in patients treated with depleting antibody therapy at the time of SOT.

Signal 1: Blockade of Antigen Recognition

Activation of the rejection response to an allograft hinges on the recognition of antigen by the host immune system. Targeting signal 1 through the use of mAbs has been used in both transplantation and autoimmunity.

Anti-CD3 Monoclonal Antibody

Muromonab-CD3 (OKT3), a mouse mAb binding to the CD3 component of the TCR signal–transduction complex, was used successfully as an induction agent for high-risk patients or for the treatment of corticosteroid-resistant acute rejection episodes as long ago as 1980. However, severe adverse effects of muromonab-CD3, such as cytokine-release syndrome (owing to the propensity of muromonab-CD3 to initially activate T cells, releasing TNF-α, and IL-2), resulted in preference for rATG and anti-CD52 agents, as outlined above. Furthermore, OKT3, an mAb of mouse origin, was limited by host production of human antimouse antibodies (HAMAs) that bind to circulating reagent molecules, neutralizing their activity. Nonactivating, therefore less toxic, humanized Fc-receptor nonbinding anti-CD3 mAbs, such as teplizumab and visilizumab, have been tested in clinical trials in autoimmune disease settings (type 1 diabetes, Crohn disease) as well as in renal and pancreatic islet transplantation.[41] Indeed, these studies have suggested a further mechanism of action with regard to anti-CD3 antibodies, and this could be helpful in the setting of transplantation: Circulating CD8 T cells isolated from patients with type I diabetes, after treatment with anti-CD3 mAb, may have regulatory function *ex vivo;* recent data have demonstrated functional human CD8 Tregs *in vivo* after administration of anti-CD3 mAb.[42] Further work is needed to elucidate the action of such agents on the immune response to both self and alloantigens to realize their full potential.

Anti-CD20 Monoclonal Antibody (Rituximab)

Rituximab is an anti-CD20, chimeric mAb that eliminates most B cells from the circulation. Originally approved to treat B-cell lymphoproliferative diseases in patients other than transplant recipients as well as to treat posttransplantation lymphoproliferative disease (PTLD), it is also now used in SOT as a treatment of antibody-mediated rejection and to desensitize patients who are receiving ABO-incompatible transplants or retransplants. However, depletion of antibody-producing cells may be incomplete because rituximab cannot target $CD20^+$ plasma cells. It has been hypothesized that the action of rituximab in allograft rejection is caused by not only depletion of plasma cells but also the effective depletion of APCs, which thus limits indirect pathway T-cell activation and a sustained immune response. Clinical administration is in conjunction with maintenance immunosuppressive agents, plasmapheresis, intravenous immunoglobulin (IVIG), and even splenectomy in some protocols.[43]

Recent work with nonhuman primate (NHP) models has shown that preemptive B-cell depletion with rituximab prevents both acute cellular rejection and antibody-mediated rejection of cardiac allografts; alloantibody was prevented from developing in blood, and complement-mediated graft injury was avoided. Not only was the B-cell response inhibited, but acute cellular rejection was also reduced by the combination of cyclosporine and rituximab, suggesting that B cells may play a role in acute cellular rejection as well. There may be a role for targeting B cells preemptively in SOT, and additional strategies to downregulate the B-cell response are under evaluation. Promising targets include BAFF and its receptor, as well as costimulatory molecules, such as CD28, CD154, and CD40.[44]

Signal 2: Blockade of Costimulation

In the absence of appropriate costimulation, partially activated T cells either become hyporesponsive to subsequent antigen-specific TCR signals (donor-specific anergy) or die by apoptosis. It has been hypothesized that the inhibition of full T-cell activation by costimulatory blockade rather than total T-cell depletion might more selectively target effector T cells and spare beneficial Tregs while avoiding the many adverse effects of nonspecific immunodepletion.

CD28:B7 (CD80/CD86) Blockade

CTLA-4 (CD152) is an inducible, T-cell surface antigen that when bound to CD80/86 receptor:ligand (B7 molecules) on APCs, delivers inhibitory signals to the activated T cell. Belatacept (LEA29Y) is a fusion protein that combines a mutated version of the extracellular binding domain of CTLA-4 with the Fc portion of IgG1, with specificity for CD80/86 expressed on APCs. Ligation of CD80/86 by CD28 (a surface antigen constitutively expressed on T cells) usually lowers the activation threshold of T cells. Belatacept has a higher affinity and slower dissociation rate from human B7 molecules (*i.e.,* CD80/86) compared with CD28, resulting in inhibition of the costimulation required for effective T-cell activation.[43]

The complexities of the human immune system present significant challenges to the translation of such agents into clinical practice: *In vivo* work indicates memory and cytotoxic $CD8^+$ T cells have different costimulation requirements for complete activation compared with $CD4^+$ naïve T cells and may therefore be more resistant to some tolerance induction strategies. Such blockade may also affect the function of Tregs as the CD28:B7 pathway has been shown to be important for their expansion and survival. However, reassuringly, data from clinical trials of belatacept in renal transplantation, albeit with small patient numbers, suggest that costimulation blockade does not interfere with Treg homeostasis.[45,46] In non-human primate models, CTLA-4 Ig prolongs pancreatic islet survival and, in combination with CD154:CD40 pathway blockade, induces indefinite acceptance of renal and heart allografts.

BENEFIT (Belatacept Evaluation of Nephroprotection and Efficacy as First-line Immunosuppression Trial), a 3-year, phase III clinical trial, randomized patients to three groups: cyclosporine, less-intensive belatacept, and more-intensive belatacept. Patients received induction with basiliximab and were maintained on mycophenolate mofetil (MMF) and corticosteroids. Patient and graft survival rates were similar across the three groups at both 1 and 2 years after transplantation. At the end of 1 year, although the incidence of acute rejection was greater for more-intensive and less-intensive belatacept compared with cyclosporine, no apparent impact on graft survival was demonstrated. At the end of 2 years, however, glomerular filtration rates (GFRs) continued to be significantly higher (15–17 mL/min) in the belatacept-treated patients. Encouragingly, belatacept-treated patients also had sustained benefits in their cardiovascular and metabolic risk profiles compared with those treated with cyclosporine, supporting the potential role of belatacept as a nonnephrotoxic alternative to CNIs.[47,48] Patients enrolled in this trial have now been followed up for 7 years, and the long-term data show that patient and graft survival and the mean eGFR are significantly higher with belatacept (both the more-intensive regimen and the less-intensive regimen) than with cyclosporine.[49]

Because of concerns about an increased post-transplant lymphoproliferative disease (PTLD) risk in Epstein-Barr virus (EBV)–seronegative patients, current belatacept trial protocols have now been modified to enroll EBV-seropositive patients only. Unfortunately, this exclusion will complicate the introduction of this drug in young patients, who might derive the maximum long-term benefit from nonnephrotoxic regimens. A significant limitation to note is that administration of belatacept requires intravenous infusion; this is not an ideal characteristic for a maintenance immunosuppressant and raises issues of patient compliance. Furthermore, the agent has a long half-life of 8–10 days and so may be difficult to appropriately titrate in transplant recipients suffering from infections.

Signal 3: Blockade of Proliferation/Differentiation

Activated T cells produce IL-2, which, in turn, binds to IL-2Rs, which are expressed only on the surface of activated cells and are not present on resting T cells. IL-2R is composed of three high-affinity transmembrane protein subunits: α (CD25), β (CD122), and γ (CD132) subunits, which are covalently linked. The α subunit is specific to IL-2R only, and it is the binding of α and β subunits that is crucial to the IL-2 signal transduction and T-cell activation that subsequently leads to proliferation and clonal expansion of T and B cells specific to alloantigen or self antigen. These cells are also stimulated to release more IL-2, further magnifying the immune response.

Anti-IL-2R Monoclonal Antibody (Basiliximab and Daclizumab)

Anti-IL-2R (anti-CD25) mAbs specifically target activated T cells but do not cause significant lymphocyte depletion and are not associated with major adverse effects compared with lymphocyte-depleting agents. However, other T-cell subtypes, including Tregs, also express CD25, and therefore the use of these agents may impact some of the natural mechanisms of immunoregulation. Basiliximab (chimeric form) and daclizumab (humanized form) have been used in renal transplantation in low-risk recipients, as defined as first allografts with living-related donors.[50,51] Basiliximab is currently the agent of choice and binds to IL-2R with similar affinity as IL-2, thereby effectively competing with IL-2 and subsequently inhibiting IL-2–driven T-cell proliferation. Basiliximab has a high volume of distribution, almost completely saturating IL-2R on the peripheral lymphocytes within 24 hours of a single dose of 2.5–25 mg in renal transplant recipients. The half-life in adults is approximately 13.4 days, and IL-2R saturation and suppression can last for 4–6 weeks.

Two meta-analyses evaluating the efficacy and safety of basiliximab in renal transplant recipients have been published.[51,52] Both studies showed that basiliximab was more effective than placebo in reducing acute cellular rejection 6 months after transplantation. However, both meta-analyses illustrated no significant differences in patient or graft survival rates between basiliximab and placebo groups at 1 year after transplantation. However, in studies involving high-risk transplant recipients (*i.e.,* high HLA-mismatch) the risk of rejection may be higher with IL-2R mAb in comparison with rATG.[53]

The highly selective and short-term immunosuppressive effects of basiliximab, which are confined to the highly immunogenic period immediately after transplantation, make this class of drug a useful substitute to steroids in early steroid-withdrawal or steroid-free regimens, as illustrated in studies with liver transplantation. Several prospective clinical trials using basiliximab induction to facilitate early steroid withdrawal or complete steroid avoidance after kidney transplantation were tried and proven safe. However, similar to alemtuzumab, the use of complete CNI avoidance protocols should be practiced with extreme caution; in several studies that withheld CNIs for any more than a very short period, despite adequate immunosuppression with IL-2R mAbs, MMF, and steroids, the acute cellular rejection rates after renal transplantation were much higher than with CNI use.[54] Thus as with ATG and alemtuzumab, patients receiving basiliximab are still exposed to chronic administration of maintenance immunosuppression and its associated comorbidities.

Glucocorticoids

Corticosteroids have complex immunosuppressive as well as antiinflammatory effects (Chapter 86). They act principally by binding to cytoplasmic glucocorticoid receptors, although at higher doses they can exhibit receptor-independent effects as well. The steroid–receptor complex translocates to the nucleus, where it is able to alter the expression of multiple cytokines through DNA-binding and by targeting transcription factors, such as AP-1 and NF-κB. Corticosteroids reduce the expression of many molecules important in the immune response, including IL-1, -2, -3, and -6; TNF-α; IFN-γ; and a number of chemokines. By inhibiting cyclooxygenase, corticosteroids are also able to reduce the production of inflammatory mediators, such as leukotrienes and prostaglandins.

Corticosteroids have been the mainstay of maintenance immunosuppression regimens for several decades. However, because of the agents' wide-ranging effects, not only involving the immune response but also a multitude of organ systems, and its direct nephrotoxicity and diabetogenic properties, in modern immunosuppressive regimens, an attempt is made to avoid or withdraw corticosteroids at the earliest possible time after transplantation (Table 81.1).

Antiproliferative Agents

Azathioprine and MMF interfere with DNA synthesis and prevent cell cycle progression. In the context of allograft rejection, this impairs the clonal expansion of alloreactive T cells.

Azathioprine is metabolized in the liver to the purine analogue 6-mercaptopurine and incorporated into DNA. By inhibiting purine nucleotide synthesis (and therefore DNA and RNA synthesis), it reduces gene transcription and prevents cell cycle progression. The effects of azathioprine are not lymphocyte specific, and patients must be monitored closely for bone marrow suppression.

MMF is metabolized in the liver to mycophenolic acid, which is a noncompetitive, reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH). Cells are able to generate purines either *de novo* by converting inosine monophosphate to guanosine monophosphate (catalyzed by IMPDH) or from guanine via the salvage pathway. The salvage pathway is less active in lymphocytes and therefore are relatively dependent on the *de novo* pathway of purine synthesis compared with other cell types. As a result, the effects of MMF are more lymphocyte specific than azathioprine, and it is less myelosuppressive. Both agents are commonly used in modern maintenance immunosuppression regimens.

Calcineurin Inhibitors

The introduction of cyclosporine in the early 1980s presented a great step forward in transplant-related immunosuppression because this was the first drug able to selectively block T-cell activation. Subsequently a second CNI, the macrolide antibiotic tacrolimus, replaced cyclosporine in most immunosuppressive regimens. Almost 99% of renal transplant recipients currently receive CNIs.[55] Both cyclosporine and tacrolimus bind cytoplasmic immunophilins (cyclophilin in the case of cyclosporine and FK506-binding protein 12 [FKBP12] in the case of tacrolimus) to form complexes that can inhibit the calcium-dependent phosphatase calcineurin, a rate-limiting enzyme in the TCR signal–transduction pathway. By preventing translocation of the transcription factor NFAT to the nucleus, calcineurin inhibition impairs upregulation of many molecules important for T-cell proliferation and the generation of an effective immune response, including the cytokines IL-2, IL-4, TNF-α, and IFN-γ, and costimulatory molecules, such as CD154. However, CNIs are well known for their nephrotoxic properties and are thought to be major contributors to chronic allograft dysfunction in renal transplantation. Thus in modern immunosuppressive regimens, an attempt is made to minimize or even replace this drug class with less harmful yet equally effective agents.

Mechanistic Target of Rapamycin Inhibitors

Sirolimus (rapamycin) and everolimus bind to the same immunophilin as tacrolimus (FKBP12), although the complexes they form are unable to interact with calcineurin. Instead they bind to the regulatory kinase mTOR, which has a critical role in cytokine receptor signal transduction. The usual actions of mTOR are to activate the ribosomal enzyme p70 S6 kinase and block an inhibitory protein 4E-BP1, both of which are required for translation of proteins necessary for progression from the G_1 (growth) phase to the S (DNA synthesis) phase of the cell cycle. Therefore inhibition of this pathway in T cells blocks the action of cytokines, such as IL-2, -4, and -15, preventing cell cycle progression and clonal expansion.

In addition to inhibiting clonal expansion of effector T cells, there is growing evidence supporting the role of rapamycin in promoting the generation and survival of Tregs, which have been shown in several animal models to be capable of preventing allograft rejection.[56] For instance, rapamycin promotes the *de novo* conversion of alloantigen-specific Tregs.[44] This is in contrast to CNIs, which inhibit such conversion. This property makes rapamycin an attractive agent to potentially promote tolerance, as discussed further in the following section.

TOLERANCE

Billingham et al. first introduced the term *transplantation tolerance* in 1953, with the report that inoculation of fetal mice with lymphoid cells from an allogeneic adult donor mouse of a different strain led to later acceptance of skin grafts from the original skin graft donors,[57] and for their seminal work Medawar received the Nobel Prize for Medicine in 1960.

The condition in which an SOT recipient exhibits a well-functioning graft and lacks histological signs of rejection after receiving no immunosuppression for at least 1 year is referred to as *clinical operational tolerance* (COT).[58] Importantly, patients demonstrating COT must also be capable of responding to other non–transplantation-related immune challenges, including infections. Over recent years, experimental models have shown that it is possible to exploit the processes by which immune homeostasis and tolerance to self antigens are maintained to induce tolerance to alloantigen (Chapter 12). The optimal outcome for patients after transplantation would be harnessing of these mechanisms to induce specific immunological unresponsiveness or tolerance to the graft, thus avoiding the adverse side effects associated with current immunosuppressive regimens (see Table 81.1).

Unfortunately, more than 5 decades of clinical experience in SOT have demonstrated that COT in humans is extremely difficult to induce intentionally and may only be possible in a subset of transplant recipients. Many successful experimental techniques can produce durable hyporesponsiveness to mismatched allografts in rodent models, but scarcely any have been successfully translated into large animal models or clinical trials. Progress in the field of transplantation tolerance has also been hampered by the

THERAPEUTIC PRINCIPLES

Mechanisms of Tolerance

Deletion

Deletion of alloreactive or autoreactive T cells can be achieved centrally in the thymus or in the periphery. Infusion of donor bone marrow into a recipient who has been conditioned with nonmyeloablative irradiation or immunotherapy enables antigen-presenting cells (APCs) to access the thymus and trigger the deletion of maturing thymocytes. In the periphery, deletion can be triggered by alloantigen recognition under suboptimal conditions, including costimulation blockade, as well as immunodepletion by activation of apoptotic cell death and cytolysis.

Anergy

This is the functional inactivation of the T-cell response to restimulation by alloantigen or self antigen and has been described both *in vivo* and *in vitro*. Some forms of T-cell anergy are also reported to result in the development of regulatory activity. Costimulation blockade, as well as inhibition of downstream proliferative pathways, can trigger anergic states in T cells.

Immunoregulation

This active process results in the regulation of one cell population by the activity of another cell population. Various populations of leukocytes have been described as having the ability to control immune responsiveness to alloantigen stimulation in both innate and adaptive immune responses. This mechanism, although well described in experimental models, has yet to be introduced therapeutically in a sustained, clinical setting.

Clonal Exhaustion

This can occur as a result of chronic antigen stimulation or antigen recognition under suboptimal conditions. The consequence is either deletion or functional inactivation of the cells responding to the recognized antigen. An example of such exhaustion can be seen in liver transplantation, where the large number of donor-derived APCs migrating from the liver to draining lymphoid tissues after transplantation can trigger this type of response.

Ignorance

This is an uncommon mechanism in the induction phase of unresponsiveness to alloantigen as it is difficult to introduce donor cells or tissue without alerting the immune system to their presence, in transplantation. This mechanism, however, does describe the natural state of some self-reactive CD4 T-cell populations found in healthy individuals with no autoimmune pathology.

lack of definitive laboratory parameters able to give a clear indication of whether a particular recipient is tolerant of his or her graft. Furthermore, COT appears to be somewhat organ dependent. Recipients of a liver graft are more capable of developing COT because of the immune-privileged status of the liver (see Fig. 81.7). Clinical experience in liver transplantation now demonstrates clear evidence that a permanent and stable immunosuppressive-free state can be safely attempted and sometimes achieved in patients who have received a liver transplant for nonimmunological liver diseases.[59] However, COT has never been reported after intestinal, islet, or whole-organ pancreas transplantation, whereas two exceptional cases of COT have been described after lung and heart transplantations.[60,61] Since the first renal transplant over 55 years ago, only sporadic cases of COT have been documented after renal transplantation in the absence of genetic identity between donor and recipient.[59]

KEY CONCEPTS

Barriers to Transplantation Tolerance

- T-cell memory
  - Presensitization—direct exposure to alloantigen (*i.e.*, pregnancy or blood transfusion).
  - Heterologous immunity—cross-reactivity in the T-cell repertoire among antiviral, antibacterial, environmental, and transplantation antigens.
  - Homeostatic proliferation—induced by immunodepletory antibodies (*i.e.*, alemtuzumab).
  - Memory T cells generated by the above mechanisms—can result in rapidly formed effector immune responses upon rechallenge. These T cells are less sensitive to T-cell depleting antibodies and costimulatory blockade and thus may be more resistant to some tolerance induction strategies.
- B-cell response
  - Recipients treated with immunodepletory antibodies display a general increase in the naïve B-cell population.
  - There is a prevalent development of alloantibody in recipients treated with depleting antibody therapy.
  - Much focus of tolerogenic strategies is on the T-cell response. However, recent data suggest that the humoral immune system may play a more significant role than previously thought, possibly contributing to more long-term outcomes. Further work in this area continues.
- Lack of tolerance signature
  - An episode of acute rejection can severely affect graft survival in most transplanted organs.
  - There is absence of validated biomarkers of tolerance or predictors of rejection.
  - It is clinically difficult to justify often high-risk tolerizing strategies in patients who would otherwise do moderately well with standard immunosuppression.

In the next section, we discuss the current clinical strategies for tolerance induction as well as much-needed future approaches to produce more short-acting, antigen-specific agents that can optimize outcomes in the clinic.

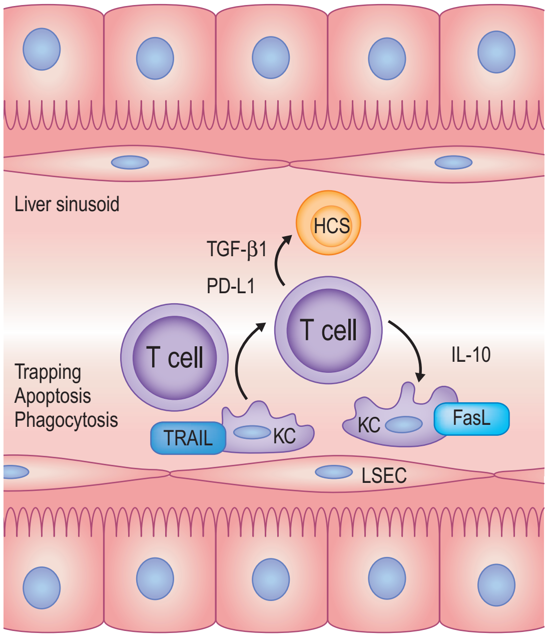
Molecule-Based Tolerogenic Protocols

The induction of COT through the administration of presumed tolerogenic drugs and subsequent immunosuppression minimization is one such strategy currently under investigation. Promising results of the first use of alemtuzumab in human subjects by Calne et al.[31,62] with low-dose cyclosporine alone as maintenance therapy introduced the concept of "*prope*" tolerance (*i.e.*, graft acceptance with reduced immunosuppression). Several groups have subsequently studied alemtuzumab induction and maintenance therapy without nephrotoxic CNI agents. Unfortunately, results of pilot studies have been poor, with high acute rejection rates (as much as 36% of recipients in one study). As discussed above, an attempt to induce donor allograft tolerance using alemtuzumab alone as an induction therapy with no maintenance immunosuppression at all resulted in all of the patients developing acute rejection within the first month after transplantation.[31] Encouragingly, physicians from the University of Wisconsin have demonstrated excellent long-term graft survival in 90% of patients maintained with only low-dose rapamycin monotherapy; these recipients had undergone alemtuzumab induction and an initial 60-day-only treatment with a CNI after transplantation to prevent acute rejection. It should be noted, however, that 50% of the patients developed alloantibody to either HLA class I or II

Tolerogenesis in the Liver

The liver is an important site for primary T-cell activation, but this takes place in an environment biased toward tolerance:

- Liver endothelium expresses adhesion molecules that facilitate the sequestration of circulating activated T cells, particularly CD8 T cells. This gives the liver a role in systemic immunoregulation.
- These activated T cells may undergo apoptosis owing to FasL and TRAIL expressed on Kupffer cells (KC) and may also be phagocytosed.
- Constitutive exposure of liver cells to traces of endotoxin and other microbial products via blood from the systemic circulation and intestine results in down-modulation of costimulatory molecules and the synthesis of IL-10 by Kupffer cells (KC) and liver sinusoidal endothelial cells (LSECS).
- Non haematopoietic liver cells, including LSECs and hepatic stellate cells (HSC) act as APCs, presenting antigen to T cells in the presence of immunosuppressive cytokines (IL-10 and TGF-β1) and inhibitory cell surface igands (PD-L1). Anergy, rather than activation is promoted. Thus immune responses to liver antigens can often result in tolerance.



Clinical Observations

- Positive cross-match or blood type incompatibility has little affect on graft survival
- HLA matching is not a prerequisite to liver transplantation
- Reduced incidence of hyperacute rejection ompared to other organs in SOT
- Frequent spontaneous recovery after severe rejection
- Acute rejection does not impact severely on long-term graft and patient survival
- Liver allograft protects other extra-hepatic allograft from rejection if derived from the same donor
- Lower overall incidence of chronic rejection that is reversible in up to 30% cases
- Clinical operational tolerance (COT) has been achieved most reliably and frequently in liver transplantation than with any other solid organ

FIG 81.7 Tolerogenesis in the Liver. The liver is an important site for primary T-cell activation, but this takes place in an environment biased toward tolerance. Liver endothelium expresses adhesion molecules that facilitate the sequestration of circulating activated T cells, particularly CD8 T cells. This gives the liver a role in systemic immunoregulation. These activated T cells may undergo apoptosis as a result of FasL and TRAIL expressed on Kupffer cells (KCs) and may also be phagocytosed. Constitutive exposure of liver cells to traces of endotoxin and other microbial products via blood from the systemic circulation and intestine results in downmodulation of costimulatory molecules and the synthesis of interleukin-10 (IL-10) by KCs and liver sinusoidal endothelial cells (LSECS). Nonhematopoietic liver cells, including LSECs and hepatic stellate cells, act as APCs, presenting antigen to T cells in the presence of immunosuppressive cytokines (IL-10 and transforming growth factor-β_1 [TGF-β_1]) and inhibitory cell surface ligands (PD-L1). Anergy, rather than activation, is promoted. Thus immune responses to liver antigens can often result in tolerance.

molecules and 40% demonstrated C4d$^+$ graft biopsies indicative of subacute humoral responses to the allograft.[39]

In 2003, investigators at the University of Pittsburgh published the results of a single center trial in which they administered an immunosuppressive regimen deemed to be tolerogenic to 82 adult kidney, liver, pancreas, and intestinal transplant recipients.[63] Their working hypothesis was that the need for continuous high-dose immunosuppression could be avoided in most cases with the use of a strong lymphocyte-depleting regimen before engraftment, followed by the administration of low-dose tacrolimus monotherapy. The goal of the induction treatment was the nonspecific removal of clones of immune cells responsible for rejection before contact with foreign donor antigens occurred while minimizing exposure to maintenance immunosuppression. At the time of publication of the study, 64% renal, 70% liver, 42% pancreas, and 54% intestinal transplant recipients were on spaced doses, but no patient could be weaned completely off immunosuppression. Nevertheless, the striking reduction in daily dosing was a step forward because it led to a significant reduction in overall immunosuppression-related morbidity.

It is important to note that other protocols based on a similar strategy have since been attempted, including post–liver transplantation protocols (the liver being an organ more capable of developing COT compared with any other). However, none of these protocols has achieved COT, nor have these protocols shown any impact on overall outcomes convincingly. In most situations, it appears that leukocyte depletion is not accompanied by a permanent and complete deletion of alloaggressive donor-reactive cells, and the establishment of a regulatory network is required to maintain tolerance.

Full Chimerism

The more robust experimental strategies for the induction of tolerance to foreign antigen utilize the mechanisms of central deletion to eliminate T-cell clones with specificity for the foreign antigens in question, thereby preventing them from entering the periphery. This can be reliably achieved by the establishment of hematopoietic chimerism through bone marrow transplantation (BMT). Stable engraftment of donor hematopoietic stem cells (HSCs) results in repopulation of the recipient thymus with donor-type thymic DCs, with the result that developing T cells with antidonor specificity are deleted by negative selection.

Full chimerism can be obtained rapidly through the ablation of the recipient's marrow and immune system with high-dose radiation and/or chemotherapy; in addition it can be induced more slowly by nonablative conditioning regimens, followed by the infusion of donor's marrow to colonize the recipient completely. This phenomenon paves the way for the onset of tolerance in the case of a subsequent SOT from the same donor.[64]

As proof of concept, numerous patients have undergone successful BMT for hematological indications and have subsequently been successfully transplanted with a kidney from the same donor, without the requirement for increased immunosuppression.

It is important to highlight that in all these cases, the use of BMT was justified on the basis of the need for treatment of hematological malignancies.

An alternative approach to achieving full chimerism and hence tolerance to donor alloantigens while avoiding GvHD or engraftment syndrome, in HLA-*mis*matched unrelated stem cell/renal transplant human recipients has been reported.[65] Results were achieved with the introduction of a mobilized cellular product enriched for tolerogenic graft facilitating cells (FCs) as well as HSCs and T cells (the treatment with HSCs in combination with FCs is termed *FCRx*) rather than just bone marrow graft alone. These bone marrow–derived FCs, which are $CD8^+$ but do not express a TCR, potently enhance engraftment of allogeneic HSCs in conditioned recipients. FCs are composed predominantly of a plasmocytoid precursor DC subpopulation, induce the generation of antigen-specific Tregs *in vitro* and *in vivo,* and have been found to effectively prevent GvHD in mice. In the first phase of this single-center clinical study, eight HLA-mismatched kidney transplant recipients were treated with FCRx and nonmyeloablative conditioning during the peritransplantation period. One year later, five recipients exhibited durable macrochimerism with no incidence of GvHD or engraftment syndrome, and were immunosuppression-free—that is, these patients were clinically operationally tolerant. *In vitro* studies indicated that chimeric donor lymphocytes were tolerized to the recipient, and a significant increase in the CD4 Treg/T effector cell population ratio was observed in these patients when compared with those who had lost chimerism. The ability to establish high levels of donor multilineage chimerism in haploidentical and highly mismatched unrelated donor–recipient pairs without the development of GvHD through the use of novel cellular therapies could have exciting therapeutic implications for disorders for which HSC transplantation can provide a "functional cure," including inherited metabolic disorders, hemoglobinopathies, and autoimmune disease, as well as in solid organ transplantation. Longer-term follow-up data on these initial patients as well as data from the enrollment of additional patients into this protocol continue to be encouraging. A phase III multicenter clinical trial is planned.

Mixed Chimerism

A promising approach is the induction of mixed hematopoietic chimerism, which can be achieved in experimental models with far less toxic induction therapy. Nonmyeloablative conditioning regimens have been applied in the clinical setting in patients who develop renal failure as a consequence of multiple myeloma. Further refinements of such protocols are being explored in experimental models. Examples of these include either a combination of depleting anti-CD4 and anti-CD8 antibodies together with mild, nonmyeloablative total body irradiation or costimulatory blockade with anti-CD154 and/or CTLA-4 Ig. When these induction protocols are followed by BMT, the result is mixed chimerism (the continued survival of both donor and recipient hematopoietic progenitor cells). Animals that have undergone these therapies have demonstrated durable tolerance to donor-type allografts and have a much lower incidence of GvHD compared with full chimeras.

In particular, the Massachusetts General Hospital (MGH) transplantation group showed in mouse and NHP models that nonmyeloablative regimens could result in transient mixed chimerism with accompanying long-term transplantation tolerance. Indeed, the same group has reported the long-term follow-up of human recipients, who underwent combined HLA-matched bone marrow and kidney transplantation for end-stage renal disease with or without multiple myeloma.[66,67]

Regulatory T Cells

There is now abundant evidence for the existence of populations of regulatory lymphocytes with the ability to suppress immune responses by other leukocytes (Chapter 18). Tregs can be divided into two populations: thymic-derived naturally occurring $CD25^+CD4^+$ cells (tTregs) and induced Tregs or iTregs that are either differentiated from $CD25^-CD4^+$ nonregulatory cells or expanded from $CD25^+CD4^+$ cells in response to antigen. Expression of the transcription factor FOXP3 is essential for the development and function of Tregs; however, tTregs and iTregs differ in origin, antigen experience, methylation patterns of FOXP3, and suppressive mechanisms. Both tTregs and iTregs have been demonstrated to play important roles in transplant tolerance.

tTregs develop within the thymus under the direction of FOXP3 and have a critical role in limiting immune responses to self antigens, as demonstrated by experimental models where mice depleted of $CD25^+CD4^+$ cells subsequently develop inflammatory bowel disease (IBD) and widespread autoimmune phenomena. Mutation of FOXP3 in humans is responsible for immune dysfunction/polyendocrinopathy/enteropathy/X-linked (IPEX) syndrome (Chapter 35). There is evidence for the involvement of Tregs in the downregulation of immune responses to tumors and chronic infections, as well as allogeneic transplants.[70]

Many strategies exist for the *in vivo* or *ex vivo* generation and/or expansion of Tregs. The most common *in vivo* approaches are based on the fact that stimulation with anti-CD3 and anti-CD28 in the presence of high concentrations of IL-2 stimulates proliferation and that exposure to antigen increases Treg frequency and/or potency by either expanding tTregs or inducing the generation of iTregs from cells that do not originally possess regulatory activity. There is a large body of data demonstrating that *ex vivo* expanded Tregs can protect allografts from rejection.[56,71]

Transplant recipients are treated with diverse immunosuppressive drug combinations, which may have a different impact on Tregs. As mentioned in the previous section, it has been demonstrated that CNIs, in particular cyclosporine, are detrimental to Tregs, whereas the mTOR inhibitor rapamycin was shown to be beneficial to Tregs both in terms of *in vivo* generation and function in mouse models and *in vitro* cultures of human Tregs. Adoptive transfer of a low number of alloantigen-specific Tregs under a cover of low-dose rapamycin was found to be capable of inducing long-term survival of heart transplants in an unmanipulated host, an outcome otherwise difficult to obtain.[72]

There are significant differences between human and mouse Tregs, in particular the differences in FOXP3 expression: In humans, FOXP3 is also expressed transiently by activated nonregulatory T cells that also upregulate CD25 expression. Thus not all $CD25^{+}FOXP3^{+}CD4^{+}$ cells will be genuine Tregs, and therefore isolation strategies based on $CD25^{hi}CD4^{+}$ are likely to be imperfect. Stable expression of FOXP3 in Tregs depends on DNA demethylation at the Treg-specific demethylated region (TSDR), a conserved, CpG-rich region within the FOXP3 locus. The TSDR is selectively demethylated in tTregs (which are more stable than pTregs), and therefore the methylation status of the TSDR region can act as a marker for the quality and stability of a Treg population. Cell-surface markers that can enrich for Tregs have also been described. In humans, $CD127^{lo}CD25^{+}CD4^{+}$ T cells are characterized by a higher level of FOXP3 expression and a more pronounced suppressive capacity.[70,71] Importantly, *ex vivo* expanded $CD25^{hi}CD4^{+}$ and $CD127^{lo}CD25^{+}CD4^{+}$ Tregs are effective at inhibiting vasculopathy in a humanized mouse model, whereas $CD127^{lo}CD25^{+}CD4^{+}$ T cells are five times more efficient than those not expressing a low level of CD127.[56]

A number of strategies for the isolation or enrichment of human Tregs have been described, but there is no consensus as to which strategy produces the optimal population for use in cell therapy applications. The most commonly used expansion protocol at present is based on stimulation by anti-CD3/anti-CD28 beads in the presence of high doses of recombinant IL-2, supplemented in some protocols with rapamycin. Despite the generation of sufficient numbers of Tregs for cellular therapy, this mode of expansion is antigen nonspecific without any enrichment steps for the cells of interest. The concept of expanding or generating donor alloantigen-reactive Tregs is much more appealing for clinical application in the setting of transplantation and a number of studies have shown that donor alloantigen-reactive Tregs are more potent on a cell-per-cell basis at controlling allograft rejection. Further work to ascertain the long-term stability and plasticity of Tregs *in vivo,* as well as the potential effects of Tregs in antitumor and antiviral immunities, as theoretically the infusion of large numbers of potent suppressive cells may compromise the immune response toward infectious pathogens and tumor cells.[73]

Several other immunomodulatory cell groups are currently under investigation as potential tolerogenic therapies, such as mesenchymal stromal cells (MSCs) and regulatory macrophages. MSCs were originally isolated from the bone marrow but can now be isolated from almost any human tissue, and they possess fascinating tissue repair and immunoregulatory properties. Preclinical models indicate that MSCs can promote engraftment of allogeneic cells, tissues, and organs as well as prevent and/or treat rejection. Although there are no published reports, to date, on their potential to induce tolerance in the setting of clinical SOT, their use as an induction therapy instead of anti-IL2R has demonstrated a lower incidence of acute rejection, decreased risk of opportunistic infection, and better estimated renal function at 1 year.[68] Regulatory macrophages have been used in two safety trials in renal transplantation. Overall, these trials demonstrated that infusion of regulatory macrophages is feasible and that there is the potential for immunosuppression minimization.[69] There are several ongoing clinical trials examining the application, safety, and efficacy of cellular therapies, including those for the prevention and treatment of GvHD in hematopoietic stem cell transplantation (HSCT) and the prevention of rejection in solid organ transplantation. (*e.g.,* the ONE Study; www.onestudy.org).[74]

Biomarkers of Rejection or Tolerance

Concerns have been raised regarding the evaluation of tolerance induction protocols, such as those using cellular therapies in recipients of kidney, heart, or pancreas, as an episode of acute rejection could severely affect graft function and survival. In these settings, most physicians are reluctant to withdraw immunosuppressive drugs in the absence of validated biomarkers of transplantation tolerance and rejection prediction. Biomarkers are thus needed to better evaluate the immune status of transplant recipients, determine the "tolerance signature" of recipients, predict and diagnose graft rejection noninvasively, and individualize immunosuppressive therapy.

Technical advances in multiparameter flow cytometry, antigen-specific lymphocyte assays, and genome-wide analyses have led to the development of powerful and more standardized immunomonitoring techniques to characterize alloimmune responses. Histological analysis remains the gold standard method by which to detect graft rejection, but graft biopsy is an invasive procedure with inherent risks and so cannot be routinely performed for surveillance purposes. It is also associated with sampling error and interpretation biases.

Molecular or cell-based biomarkers are being developed as alternative surveillance methods.[20,75] At present, it is notable that for the many biomarkers identified, there are discrepancies among data from different laboratories investigating the same parameter. This is likely caused by differences in recipient and donor populations, clinical management, and the laboratory techniques used to perform the assays. Therefore it is of great importance that the assays used to detect biomarkers are optimized, validated, and standardized and that candidate biomarkers are investigated in large patient cohorts from different transplantation centers using the same shared and validated assays.[76]

ON THE HORIZON

Initiatives in Clinical Utilization of Tolerance

- Clinical introduction of antigen-specific regulatory T-cell therapy
- Identification of tolerance signatures and predictors of rejection
- Use of immunomodulatory stem cell populations (*i.e.,* mesenchymal stromal cells)

MULTIPLE-CHOICE QUESTIONS

1. The transfer of an organ between genetically identical individuals is termed:
   A. An autograft
   B. An allograft
   C. A xenograft
   D. An isograft
   E. A haplograft

2. The proportion of T cells that are capable of directly recognizing allogeneic major histocompatibility complex–peptide complexes is:
   A. Low before transplantation
   B. Only the memory T-cell subpopulation
   C. About the same as the frequency directed against a nominal antigen
   D. Zero given that T cells are self-restricted
   E. Approaching 10% of T cells

3. What mechanism is responsible for the presence of memory T cells reactive against a graft in a patient receiving his or her first transplant?
   A. Previous blood transfusion
   B. Previous pregnancy
   C. Heterologous immunity
   D. Direct allorecognition
   E. All of the above

82

Immune Reconstitution Therapy for Immunodeficiency

Luigi D. Notarangelo, Sung-Yun Pai

Following the discovery of the major human leukocyte antigens (HLAs) in 1958, hematopoietic stem cell transplantation (HSCT) came into practice to provide treatment for a variety of congenital and acquired disorders. Cure of an infant with severe combined immunodeficiency (SCID) in 1968 was the first successful experience in HSCT, marking the beginning of a new era in medicine. Shortly thereafter, partial success was achieved also with HSCT in a child with Wiskott-Aldrich syndrome (WAS).

For many years, the successful use of HSCT in severe primary immune deficiency (PID) was largely restricted to transplantation from HLA-matched related donors (MRDs), as HSCT from mismatched related family donors (MMRDs), usually represented by haploidentical parents, was followed by severe complications, graft-versus-host disease (GvHD) in particular. In the late 1970s, it was demonstrated in animal models that removal of mature T lymphocytes from the graft obtained from mismatched marrow allowed successful reconstitution upon injection into lethally irradiated recipient animals. This important achievement opened the way to a broader use of HSCT in severe forms of PID. More recently, transplantation of hematopoietic stem cells (HSCs) from volunteer matched unrelated donors (MUDs) and of umbilical cord blood (UCB) has been increasingly used in individuals with PID. Overall, since 1968, over 2000 transplantations have been performed in patients with PID, most of them in children with SCID.[1,2] The increasing number of transplantations over the years reflects an increased awareness of PID, the broader availability of diagnostic tools (including newborn screening for SCID), improved outcomes as a result of advances in supportive and critical care before and after HSCT, increasingly improved strategies to prevent GvHD, and the greater availability of MUD and UCB for transplantation.

HEMATOPOIETIC STEM CELL TRANSPLANTATION: GENERAL CONSIDERATIONS

Sources of Hematopoietic Stem Cells for Transplantation

Several sources of HSCs are available for transplantation (Table 82.1). HSCs can be retrieved from bone marrow, peripheral blood, or UCB (Chapter 2). Bone marrow stem cells are most commonly obtained by multiple aspirations along the iliac crests, usually while the donor is under general anesthesia. The volume of bone marrow that is obtained may vary between 500 mL and 1 L or even more, depending on the type of transplant (HLA-identical or T cell–depleted) and the weight of the recipient. Blood group matching for ABO antigens is not required for HSCT, as mature red blood cells (RBCs) or anti-ABO antibodies can be removed by RBC depletion and plasma depletion, respectively. In the case of HLA-identical transplantation, marrow stem cells are then injected intravenously without further manipulation into a central line in the recipient. In the case of mismatched transplantation, bone marrow cells are usually T cell depleted *in vitro* (see below); stem cells are then enumerated and injected intravenously. More recently, injection of unmanipulated bone marrow cells from MMRD, followed by *in vivo* administration of cyclophosphamide to prevent GvHD, has been also used.[3]

HSCs can also be retrieved from peripheral blood, following *in vivo* administration of granulocyte–colony-stimulating factor (G-CSF) to the donor, usually at the dosage of 10 μg/kg/day for 5 days, which allows mobilization of stem cells. In this case, stem cells can also be purified by positive selection (see below), enumerated, and injected.

Finally, UCB is another rich source of HSCs. At birth, cord blood is collected in a heparinized medium and stored in liquid nitrogen, with small aliquots preserved for HLA typing. Whenever sufficient compatibility is identified between a patient and stored cord blood, the latter is thawed and injected into the recipient without further manipulation. With this procedure, the number of HSCs that can be transplanted is dictated by their concentration in the cord blood sample and by the volume of the sample itself. More recently, *in vitro* expansion of cord blood stem cells, and transplantations with multiple cord blood units, have been attempted to overcome this limitation.

Donor Selection and Manipulation of the Graft

HSCT From a Related HLA-Identical Donor

The use of unfractionated stem cells from an HLA-identical sibling offers the best chance of rapid engraftment and immune reconstitution. In such cases, the HLA-identity between recipient and donor minimizes the risk of GvHD. Furthermore, the mature T cells contained in the graft provide a first line of immune reconstitution after transplantation, as they may expand and lead to a rapid increase in the number of circulating T lymphocytes as early as 2 weeks after HSCT. Engraftment of these mature T cells transplanted with the bone marrow of an MRD is particularly important in infants with SCID, as it is early evidence of immune reconstitution in a severely immunocompromised host.

TABLE 82.1 Sources of Hematopoietic Stem Cells for Transplantation

Hematopoietic Stem Cell Transplantation (HSCT) From a Related Donor

- Bone marrow from a human leukocyte antigen (HLA)–genotypically identical sibling
- Bone marrow from an HLA-phenotypically identical family member
- Bone marrow from a haploidentical parent
  - T cell depleted by negative selection with soybean lectin agglutination and rosetting with sheep red blood cells (E-rosetting)
  - T cell depleted by negative selection with monoclonal antibodies
  - Positive selection of CD34$^+$ cells

HSCT From a Matched Unrelated Donor

- Unmanipulated bone marrow
- T cell–depleted bone marrow by means of positive selection of CD34$^+$ cells
- Positively selected peripheral blood CD34$^+$ cells

HSCT From an Unmanipulated Related or Unrelated Cord Blood

KEY CONCEPTS

Sources of Stem Cells and Selection of Donors for Hematopoietic Stem Cell Transplantation in Primary Immunodeficiencies

- Sources of hematopoietic stem cells (HSCs) for transplantation include bone marrow, peripheral blood, and cord blood.
- If the donor is a genotypically human leukocyte antigen (HLA)–identical sibling, unmanipulated bone marrow is used as source of stem cells.
- Whenever the donor is HLA-mismatched to the recipient, T-cell depletion must be performed to eliminate mature T lymphocytes from the graft. Methods for T-cell depletion of the bone marrow include use of soybean lectin agglutination and E-rosetting, depletion with monoclonal antibodies (mAbs), and positive selection of stem cells.
- Cord blood is a rich source of stem cells. However, the volume of cord blood is limited, so its use is mainly restricted to young patients.
- The number of volunteers included in Bone Marrow Donor Registries is expanding. Consequently, there is a continuous increase in the number of matched unrelated donor (MUD) transplantations performed for patients with primary immunodeficiencies.
- Whenever cord blood or MUD stem cells are used, conditioning regimen must be given to the recipient before transplantation to facilitate engraftment of donor stem cells.
- Therapeutic options for patients with severe combined immunodeficiency (SCID) and other severe forms of primary immunodeficiency (PID) include transplantation from HLA-genotypically identical donor, mismatched related donors (MMRD), and MUDs.

HSCT From a Haploidentical Donor

Unfortunately, the option of related HLA-identical HSCT is limited only to a minority of patients. When no such donor is available, stem cell transplantation from a haploidentical parent should be considered, particularly in infants with SCID.

The rationale for haploidentical HSCT is based on the ability of donor-derived stem cells to repopulate the recipient's vestigial thymus and give rise to fully mature T lymphocytes. Indeed, this is a life-saving procedure that has been successfully applied to several hundreds of infants with SCID.[1,2]

However, this procedure requires careful removal of T lymphocytes from the graft, as these would otherwise cause severe GvHD. Several methods are available to attain T-cell depletion.

In the past, the method of soybean lectin agglutination and E-rosetting was frequently used. With this method, soybean lectin allowed agglutination of the majority of mature marrow cells, which were removed by sedimentation. Further depletion of T lymphocytes was achieved by rosetting with sheep erythrocytes (E-rosetting technique) and density gradient centrifugation. Importantly, T-cell depletion by soybean lectin agglutination and E-rosetting maintains all immature marrow cells in the final preparation.

T-cell depletion can also be achieved by incubation of bone marrow with monoclonal antibodies (mAbs) to T lymphocytes plus complement. Campath-1 G, Leu 1, and other mAbs have been used for this purpose, but the degree of T-cell depletion that is achieved with these agents is less effective than with the soybean lectin and E-rosetting, and therefore a higher incidence of GvHD has been reported. More recently, use of mAbs directed against the αβ form of the T-cell receptor (TCR) and against CD19 has entered clinical practice, with excellent results.[4]

However, the most common method to obtain transplantable HSCs is represented by positive selection of CD34$^+$ cells using mAbs. This method allows very robust depletion of mature T cells; however, it also removes immature CD34$^-$ cells and other cells (especially stromal marrow cells) that can facilitate stem cell engraftment.

Selection of the best donor is another important aspect of T cell–depleted haploidentical HSCT for SCID. In general, the donor is represented by one of the parents, since the volume of bone marrow that can be collected is much higher than it would be if a haploidentical sibling were to serve as donor. Maternal T-cell engraftment *in utero* is a common finding in infants with SCID and has been observed in almost 40% of patients with SCID. In such cases, T cell–depleted HSCT should be performed using the mother as donor, if possible, since transplantation from the father might cause a graft-versus-graft reaction.

In Utero Haploidentical HSCT

The identification of a growing number of immunodeficiency-causing genes has resulted in continuous improvement in prenatal diagnosis, which, in most cases of severe immunodeficiency, can now be accomplished on chorionic villi DNA at 10–11 weeks of gestation. This has prompted prenatal transplantation of parental positively selected CD34$^+$ stem cells into the peritoneum of fetuses prenatally diagnosed with SCID, under ultrasound guidance.

The rationale underlying *in utero* HSCT is based on a lower risk of graft rejection resulting from decreased fetal immunocompetence (although this consideration is not relevant in the case of fetuses with SCID), a presumed induction of tolerance to paternal antigens (which might favor successful engraftment after postnatal transplantation from the same donor), the predicted competition between donor and autologous stem cells at a time when several empty niches should be available for stem cell engraftment, the potential ability to provide preemptive treatment (thus reducing the risk of postnatal infection), and the lower cost of the procedure that does not require prolonged hospitalization. However, *in utero* HSCT is associated with the potential risks of fetal loss and of GvHD. Finally, if maternal T cells had engrafted into the fetus with SCID, transplantation of paternal CD34$^+$ cells might cause graft-versus-graft reaction.

In a series of five *in utero* HSCT performed at the University of Brescia, Italy, all three cases with B^+ SCID survived, with evidence of T-cell reconstitution. However, transient or no immune reconstitution was observed in two fetuses with B^- SCID. The use of *in utero* HSCT for SCID is now largely unjustified, also in consideration of the fact that newborn screening allows rapid identification of infants with SCID and permits rapid referral to HSCT, with long-term survival that exceeds 90%.[5]

HSCT From Matched Unrelated Donors

Since the first successful HSCT performed in 1977 in an infant with SCID, HSCT from MUD has been increasingly used to treat severe PID. MUD HSCT has been shown to be more effective than T cell–depleted HSCT in patients with immunodeficiencies other than SCID,[1] and it has been successfully used also in infants with SCID.[6]

Transplantation from MUD has been facilitated by the increasing number of volunteer donors included in registries worldwide. In addition, advances in the quality of the techniques used for HLA typing permits this identification of an optimal MUD and reduction in the risk of GvHD. As of April 2016, more than 28 million donor volunteers and UCB units were included in the Bone Marrow Donors Worldwide (BMDW) registry. At present, it takes only a few weeks to identify a MUD. However, the probability of finding a suitable donor is lower for selected ethnic or racial groups that are poorly represented among volunteer donors.

Importantly, MUD HSCT requires use of a preparative chemotherapy regimen in the recipient (even in the case of SCID) and GvHD prophylaxis (because of likely disparity between donor and recipient at minor histocompatibility loci), whereas neither one is necessary for related HLA-identical HSCT in SCID infants.

HSCT Using Unmanipulated Cord Blood

As opposed to MUD HSCT, which requires identification, willingness, and medical clearance of an adult volunteer, stored cord blood is readily available as a source of stem cells for transplantation. In addition, the risk of GvHD at any given degree of HLA matching is lower when using cord blood compared with MUD HSCT so that greater HLA disparity with the recipient can be tolerated. However, the number of cells contained in any defined unit is still a major limitation of cord blood. Low cell dose is not usually a problem for transplants performed in infants with SCID or other severe forms of immune deficiency because of the low weight of the recipient. Indeed, unrelated umbilical cord stem cell transplantation has been successfully used in dozens of patients with severe PID.[7] In practice, an unrelated HSC donor should be simultaneously searched for in cord blood banks and in bone marrow donor registries for patients lacking an HLA-identical sibling HSC donor. The option of performing cord blood transplants should be based on urgency of the transplantation, the cell dose required, and the number of HLA disparities.

As for HSCT from MUD, transplantation using cord blood usually requires pretransplantation conditioning and GvHD prophylaxis, irrespective of the underlying disease.

Complications of Hematopoietic Stem Cell Transplantation

A variety of complications can compromise the success of HSCT. Among these, incompatibility between donor and recipient can lead to graft rejection by the host immune system or to GvHD caused by alloreactivity of donor-derived lymphocytes to the recipient's cells. Furthermore, conditioning regimens can cause toxicity of several organs. Myeloablative regimens cause anemia, thrombocytopenia, and leukopenia. Consequently, supportive treatment with RBC and platelet transfusions is necessary during the aplastic phase. Finally, the leukopenia predisposes the patient to an increased risk of life-threatening bacterial or fungal infections.

The frequency and severity of these complications depend on the type of transplant, the possible use of a conditioning regimen, and specific considerations related to the underlying disorder and to the clinical status of the recipient before transplantation.

KEY CONCEPTS

Rejection of Donor Stem Cells by the Host Immune System and Reaction of Donor's T Lymphocytes to the Host

The host T cells are responsible for the elimination of donor stem cells, regardless of the degree of human leukocyte antigen (HLA) compatibility. Under these circumstances, other than in patients with severe combined immunodeficiency (SCID), a chemotherapy-based conditioning regimen must be used before transplantation to allow for donor stem cell engraftment.

If T cells are present in the graft, and especially if there is HLA-incompatibility between the donor and the recipient, the donor's T lymphocytes may react to host alloantigens and cause graft-versus-host disease (GvHD).

Risk factors for GvHD include HLA-mismatch between donor and recipient, older age at transplantation, gender mismatch, and previous viral infections.

GvHD may develop early after transplantation (acute GvHD), or at 100 days or more after transplant (chronic GvHD). GvHD is one of the major causes of death and long-term disability after stem cell transplantation.

Prevention is the best approach to the management of GvHD. Prevention of GvHD is based on selection of optimal donor and vigorous T-cell depletion in the case of HLA mismatch between the donor and the recipient. Immunosuppressive drugs, such as cyclosporine, are another potent form of GvHD prevention.

Graft Rejection

Graft rejection reflects the presence of immunocompetent cells in the host that specifically recognize and react to donor-derived stem cells. Several factors influence the likelihood of graft rejection, in particular *(i)* the degree of immunocompetence of the host; *(ii)* the degree of HLA disparity between donor and recipient; *(iii)* the number and source of stem cells infused; *(iv)* the type of conditioning regimen used; and *(v)* the possible presensitization of the host to donor histocompatibility antigens.

In the case of infants with SCID, graft rejection is an unlikely event because of the virtual lack of T cells that characterizes these conditions. However, natural killer (NK) cells are present in several forms of SCID and may contribute to graft rejection. Indeed, among infants with SCID who received HSCT without conditioning chemotherapy, reduced overall survival and increased requirement of additional procedures have been observed in those with NK^+ SCID compared with NK^- SCID (Fig. 82.1).[8] In other forms of PID, there is sufficient immune function in the host to allow for rejection of donor-derived stem cells, unless an appropriate conditioning regimen is used before HSCT.

In children with nonmalignant disease, the most commonly used myeloablative conditioning regimen consists of busulfan

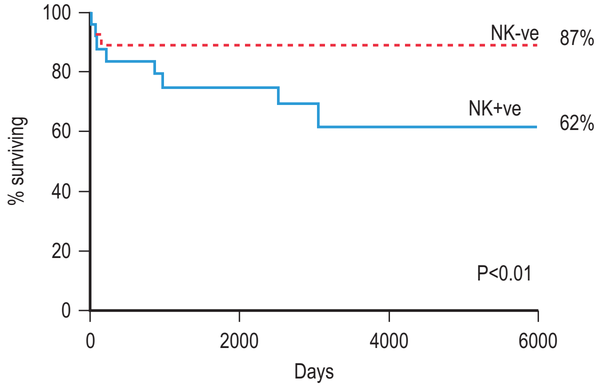

FIG 82.1 Kaplan-Meyer survival curve after nonconditioned transplantation for infants with severe combined immunodeficiency (SCID) with normal natural killer (NK) cell count (NK$^+$) or with lack or markedly reduced number of NK cells (NK$^-$). (With permission from Hassan A, Lee P, Maggina P, et al. Host natural killer immunity is a key indicator of permissiveness for donor cell engraftment in patients with severe combined immunodeficiency. J Allergy Clin Immunol 2014;133:1660–6.)

TABLE 82.2 Staging and Grading of Acute Graft-Versus-Host Disease (aGvHD)

Stage	Skin	Liver (Bilirubin)	Gastrointestinal system (GI) (Stool output)
0	None	<2 mg/dL	Adult: <500 mL/day Child: <10 mL/kg/day
1	Rash <25% BSA	2–3 mg/dL	Adult: 500–999 mL/day Child: 10–19.9 mL/kg/day or persistent nausea, vomiting, or anorexia, with a positive upper GI biopsy
2	Rash 25–50% BSA	3–6 mg/dL	Adult: 1000–1500 mL/day Child: 20–30 mL/kg/day
3	Rash >50% BSA (generalized erythroderma)	6.1–15 mg/dL	Adult: >1500 mL/day Child: >30 mL/kg/day
4	Generalized erythroderma with bullous formation	>15 mg/dL	Severe abdominal pain with or without ileus

Grade

Grade 0	No stage 1–4 of any organ
Grade 1:	Stage 1 or 2 skin involvement; no liver or gut involvement
Grade 2:	Stage 1–3 skin involvement; Grade 1 liver or gut involvement
Grade 3:	Stage 2 or 3 skin involvement
Grade 4:	Stage 1–4 skin involvement; stage 2–4 liver or gut involvement

and fludarabine, with or without the addition of antithymocyte globulin (ATG) or anti-CD52 (alemtuzumab) mAb. However, infants and children with preexisting organ damage are highly sensitive to the toxic effects of drugs. In these cases, reduced intensity regimens are preferred. To this purpose, lower doses of busulfan are used. Treosulfan is an alternative to busulfan and has reduced toxicity.[9] Finally, the combination of fludarabine and melphalan is another common form of reduced-intensity conditioning.

Acute Graft-Versus-Host Disease

Acute GvHD (aGvHD) is the result of alloreactivity of donor-derived T lymphocytes versus the recipient's antigens and is one of the most severe complications of HSCT. It may occur as early as 1 week after HSCT and is potentially fatal. Clinical manifestations of aGvHD include maculopapular skin rash (that tends to be confluent), diarrhea, and liver abnormalities (hepatomegaly, elevated liver enzymes, increased levels of conjugated bilirubin).[10] The disease may progress to severe skin manifestations, with exfoliative dermatitis, and significant liver and gut damage (with intractable watery or bloody diarrhea, protein-losing enteropathy, and abdominal pain). In the most severe cases, leakage of intravascular fluids into the interstitium (so-called third space filling) leads to generalized edema. Bone marrow aplasia and a high susceptibility to infections (including reactivation of herpesvirus infections) are also often observed in severe aGvHD.

The severity of aGvHD is evaluated according to grading (Table 82.2). Major risk factors for aGvHD include HLA-mismatch between donor and recipient, older age of the recipient or donor, gender mismatch, and stem cell source.[10] However, aGvHD may also be observed following related HLA-identical HSCT, particularly when a conditioning regimen is used.

Finally, transfusion-associated aGvHD is a very severe complication after HSCT, which can be effectively prevented by using irradiated (1500–3000 rad) and filtered blood derivatives.

Chronic Graft-Versus-Host Disease

Chronic GvHD (cGvHD) has traditionally been defined as symptoms that persist or appear after 100 days since the time of transplantation. As the types of donor, stem cell sources, and conditioning regimens have changed, it is now recognized that symptoms of aGvHD can present later than 100 days and that cGvHD is better defined by its distinct clinical manifestations rather than the time of onset alone. These clinical manifestations include skin changes (scleroderma-like lesions, hyperpigmentation, hyperkeratosis, skin atrophy, ulcerations), tissue fibrosis and limitation of joint motility, fibrosis of exocrine glands ("sicca syndrome"), fibrosis of lungs and liver, increased susceptibility to infections, immune dysregulation, and autoimmunity.[10] Consequently, cGvHD poses a major burden on the patients' quality of life and can be fatal.

Although the incidence of cGvHD is lower in children than in adults treated by allogeneic HSCT, the risk factors and the spectrum of clinical manifestations are similar.

Acute GvHD represents a major risk factor for cGvHD, and yet cGvHD can be observed even without preceding aGvHD, and when present, it does not represent merely the continuation of aGvHD. Older age of the recipient at HSCT, transplantation from a multiparous female donor into a male recipient (with reactivity to Y chromosome-associated antigens), and incompatibility at minor histocompatibility loci represent additional risk factors for cGvHD.[10] Furthermore, use of peripheral blood stem cells carries an increased risk of cGvHD compared with use of bone marrow stem cells.

Prevention of GvHD

Prevention is the most effective approach to GvHD, and use of a fully matched donor remains the best method of prevention. Alternatively, if a related HLA-mismatched donor is used for transplantation, it is essential that the graft is vigorously T-cell depleted.

Whenever a conditioning regimen is used in the transplantation protocol, pharmacological prophylaxis of GvHD must also be included, even in the case of HSCT from a related HLA-identical donor.

Long-standing approaches to prevention of GvHD include cyclosporine daily for 6 months or methotrexate (15 mg/m^2 on the first day after HSCT, and then 10 mg/m^2 at days +3, +6, and +11 after transplantation), or a combination of the two. Newer regimens substitute another calcineurin inhibitor, tacrolimus, for cyclosporine. Serotherapy with ATG or alemtuzumab is often included in the preparatory regimen, with the aim of reducing the risk of GvHD. The timing of administration of alemtuzumab as part of the preparatory regimen has opposed effects on the prevention of aGvHD and the speed of T-cell reconstitution. In particular, use of alemtuzumab in the days that immediately precede transplantation has more potent effects on aGvHD prevention but is associated with delayed T-cell reconstitution, whereas the opposite is observed when the drug is administered a few weeks before HSCT. Finally, mycophenolate mofetil and methotrexate can also be used to prevent GvHD.

Attempts to prevent cGvHD have been less satisfactory. In particular, use of a prolonged immune suppression after transplant does not decrease the incidence of cGvHD.

Treatment of GvHD

Once GvHD has developed, treatment is mainly based upon the use of immunosuppressive drugs. Corticosteroids remain the first-line therapy and are usually effective, especially for mild and moderate forms of aGvHD. Second-line therapy includes ATG, mycophenolate mofetil, cyclosporine, or tacrolimus. mAbs, such as anti-CD25 (daclizumab), are also used. However, the efficacy of second-line agents in severe or steroid unresponsive aGvHD is limited.

Treatment of cGvHD is also based on immunosuppression, but with limited efficacy.[11,12] Topical steroids and calcineurin inhibitors may alleviate mucosal and skin symptoms. Systemic steroids have been shown to improve survival, but at the risk of significant adverse effects. Ursodeoxycholic acid may be useful in cGvHD with significant liver involvement. Extracorporeal photopheresis can be used with the goal to induce tolerance; typically, its benefits, if present, are delayed until 2–3 months after initiation of treatment. Use of hydroxychloroquine, mycophenolate mofetil, anti-TNF-α mAb, etanercept (a recombinant form of soluble tumor necrosis factor [TNF]-receptor), and anti-CD20 antibody (rituximab) remains investigational.

Infections

Infections represent one of the major complications following HSCT. Patients with severe PID are intrinsically highly susceptible to infections. In infants with SCID and with other forms of combined immune deficiency, viral and opportunistic infections can develop before transplantation and are one of the factors that adversely affect the outcome of HSCT itself.[2] Regardless of the type of underlying PID, T cell–depleted HSCT carries a high risk of infections because of the longer time required to achieve immune reconstitution. Furthermore, use of a pretransplant conditioning regimen with myeloablative and immunosuppressive drugs, and GvHD prophylaxis, contribute to the increased susceptibility to infections after HSCT.

Strict isolation of the patients during and after HSCT, and prophylactic administration of antibiotics, have been associated with a better survival rate, particularly after related HLA-mismatched transplantation for SCID.[3] In spite of this, infections remain the major cause of death. Challenging viruses in infants with SCID include adenovirus, cytomegalovirus (CMV), parainfluenza type III virus, and Epstein-Barr virus (EBV). In particular, CMV infection after HSCT can cause interstitial pneumonia, enteritis, hepatitis, and encephalitis. EBV can also cause lymphoproliferative disease. Filtering of blood derivatives removes leukocytes and thus reduces the risk of transfusion-associated infections. Several antiviral drugs (acyclovir, ganciclovir, foscarnet, cidofovir) are now available and have good results, especially against CMV,[13] and preemptive administration of anti-CD20 mAb is efficacious in the prevention of EBV-driven lymphoproliferative disease. Furthermore, transfusion of virus-specific cytotoxic T lymphocytes (CTLs) represents another important resource to fight severe viral infections.[14]

Pneumocystis jiroveci is a common cause of pneumonia in severely immunocompromised patients. Treatment is based on intravenous cotrimoxazole (20 mg/kg/day).

Aspergillus infection is a severe complication in patients with chronic granulomatous disease (CGD) and in patients with profound neutropenia. Voriconazole offers some advantage compared with liposomal amphotericin B for treatment of invasive aspergillosis, whereas prophylactic itraconazole reduces the incidence of fungal infections in patients with CGD before transplantation.

Bacterial infections are usually amenable to successful treatment, if the pathogen is identified, and appropriate and aggressive use of antibiotics is initiated. Prophylactic administration of immunoglobulins (Igs) following HSCT also reduces the frequency and severity of infections. Administration of Bacille Calmette-Guérin (BCG) vaccine at birth to prevent tuberculosis is still practiced in many countries worldwide. In severely immunocompromised infants who undergo HSCT, this live vaccine may cause disease, which often manifests at the time of engraftment with local and systemic immune reconstitution inflammatory syndrome (IRIS).

Toxicity Related to Conditioning Regimen

Chemotherapeutic agents that are used in the conditioning regimen of HSCT often cause significant short-term and long-term toxicity. Chemotherapeutic drugs that damage the liver vascular endothelium, particularly busulfan and cyclophosphamide, can cause veno-occlusive disease (VOD), which is clinically marked by painful hepatomegaly, jaundice, ascites, fluid retention, and weight gain and can ultimately result in fatal multiorgan failure (MOF). Defibrotide is the most effective agent studied to date in the treatment of VOD. Busulfan can also cause seizures and lung damage. Cyclophosphamide can cause hemorrhagic cystitis, a syndrome of inappropriate antidiuretic hormone secretion, or more rarely, cardiac disturbances.

Long-term hormonal complications are more common when total body irradiation (TBI) is used. However, the busulfan and cyclophosphamide regimen can cause delayed puberty or sterility, and thyroid dysfunction is frequently observed, even in patients who have not received TBI. Delayed or incomplete tooth eruption is also a possible consequence of conditioning regimens. Effects on final height and growth, as well as long-term neurocognitive effects, are emerging as more children are treated and followed up. Patients with defects of DNA repair (*e.g.*, some forms of SCID) are particularly at risk for drug-related toxicities.

CLINICAL PEARLS

Considerations of Stem Cell Transplantation Unique to Severe Combined Immunodeficiency (SCID)

Patients with SCID are strongly impaired in their ability to reject allogeneic cells, including stem cells. Therefore no chemotherapy is required in these patients in order to achieve T-cell reconstitution following stem cell transplantation.

The quality and the kinetics of T-cell reconstitution following stem cell transplantation depend on the type of transplant.

If unmanipulated bone marrow from genotypically human leukocyte antigen (HLA)-identical related donor is used, mature T cells contained in the graft expand as early as 2 weeks after transplantation and provide a rapid source of immune competence.

A similar phenomenon is also observed following unmanipulated matched unrelated donor (MUD) transplantation. In this case, however, drugs used in conditioning regimen and for prevention of graft-versus-host disease (GvHD) decrease the degree of early expansion of donor-derived T cells.

In contrast, appearance of naïve T cells occurs only at 3 months or more after transplantation, regardless of degree of HLA matching between donor and recipient. Consequently, following haploidentical transplantation, there is a prolonged period during which the recipient remains lymphopenic and at high risk of infections.

In the absence of pretransplant conditioning, following haploidentical transplantation for SCID, engraftment is usually restricted to T lymphocytes. This may cause persistent B-cell dysfunction. Furthermore, patients with natural killer (NK)$^+$ SCID may show some ability to reject stem cells from HLA-mismatched donors. For these reasons, several centers include use of conditioning regimen for the hematopoietic stem cell transplantation (HSCT) in babies with SCID who do not have a matched related donor available.

HSCT for SCID

General Considerations

SCID is a medical emergency and is uniformly fatal unless promptly diagnosed and successfully treated. With a few exceptions in which alternative strategies (gene therapy, enzyme replacement therapy) can be used, allogeneic HSCT represents the most effective form of treatment for these disorders.

SCID is also a unique situation in which the virtual lack of T lymphocytes strongly impairs the ability of the recipient to reject the graft. Furthermore, donor-derived lymphoid progenitor cells have a striking advantage for *in vivo* T-cell differentiation. Consequently, use of pretransplantation chemotherapy and immune suppression is not required to attain T-cell reconstitution. However, although there is a general consensus that no conditioning is needed for HSCT from an HLA-identical related donor, there is controversy as to whether chemotherapy should be used for T cell–depleted mismatched HSCT. Although use of conditioning chemotherapy carries the risk of drug-related toxicity, it favors the engraftment of donor-derived stem cells and may lead to a better recovery of humoral immunity and of improved thymopoiesis. In approximately 30% of the cases, unconditioned, T cell–depleted MMRD transplantation may fail to induce T-cell reconstitution in infants with SCID. In this case, booster transplants without chemotherapy may be helpful. A recent report analyzed the outcome of such a procedure.[15] Among 49 patients with SCID who received such booster transplants at Duke University Medical Center, 31 (63%) survived for up to 28 years. Older age at HSCT and persistence of preexisting infections represented significant risk factors for death. In several patients, the use of two parents as sequential donors was associated with immune reconstitution.

In contrast, chemotherapy is typically used for HSCT from unrelated donors and—irrespective of donor type—for “leaky” forms of SCID with presence a significant number of autologous, partially functioning T lymphocytes.

Survival Following HSCT for SCID

The two largest series of patients with SCID treated by HSCT in Europe and in North America included 699 and 240 cases, respectively.[1,2]

In the European study, which included transplantations performed between 1968 and 2005, 203 patients received HSCT from genotypically (n = 135) or phenotypically (n = 68) identical related donors, with 10-year overall survival rates of 84% and 64%, respectively. This figure is clearly superior to the 54% survival rate observed among 415 patients who had received related HLA-mismatched HSCT. Finally, in this study, 81 patients received HSCT from MUDs, and 66% survived.[1] In the North American study, which included transplantations performed between 2000 and 2009, the overall 5-year survival rate was 74%.[2] In particular, the survival rate was highest among recipients of HSCT from HLA-matched sibling donors (MSDs) (97%), followed by unconditioned HSCT from MMRDs (79%), HSCT from URDs (74%), HSCT from MMRDs with conditioning (66%), and HSCT from UCB (58%).

Survival after HSCT for SCID has improved over the years (Fig. 82.2),[1] reflecting more effective treatment and prevention of disease-related and transplantation-associated complications, such as infections and GvHD. In particular, according to the European study,[1] the current survival rate after HSCT from HLA-identical related donors is 90%, whereas 3-year survival after HSCT from related HLA-mismatched donors has improved from 49% in transplantations performed up to 1994 to 69% in those performed between 1995 and 1999. However, no further improvement in survival has been observed since that time.

Several factors influence survival after HSCT for SCID. In particular, younger age at transplantation leads to superior survival. In the North American study, among 68 infants who were treated before 3.5 months of life, 64 (94%) survived.[2] Similarly high survival rates were observed also among infants older than 3.5 months with no history of infections or whose infections had resolved before HSCT (90% and 84% 5-year survival rates, respectively).[2] Collectively, these data emphasize the importance of early diagnosis to prevent infections and provide strong support to newborn screening for SCID. For patients of any age who do not have MSDs and have an active infection at the time of HSCT, a higher survival rate (65%) is observed with unconditioned transplantation from MMRDs.[2]

The SCID genotype and phenotype may also affect the outcome of HSCT. In the European series, infants with B^+ SCID had superior 10-year survival after HSCT compared with infants with B^- SCID (70% vs 51%, respectively; Fig. 82.3),[1] although no significant difference in survival between these two groups of infants with SCID was observed in the North American study.[2] Furthermore, haploidentical transplantation without conditioning or with immunosuppression only in patients with recombinase activating gene (RAG) or Artemis deficiency is associated with a high risk of graft failure or of incomplete T-cell reconstitution.[16]

FIG 82.3 Cumulative probability of survival in patients with $T^- B^-$ or $T^- B^+$ severe combined immunodeficiency (SCID) after hematopoietic stem cell transplantation (HSCT). (With permission from Gennery AR, Slatter MA, Grandin L, et al. Transplantation of hematopoietic stem cells and long-term survival for primary immunodeficiencies in Europe: entering a new century, do we do better? J Allergy Clin Immunol 2010;126:602-10.e1–11.)

Factors that may contribute to such poor outcome may include the presence of autologous NK cells that may mediate graft rejection. Consistent with this, in a UK series of 77 infants with SCID who received HSCT, survival rate was higher among patients with NK^- SCID than among recipients with NK^+ SCID (see Fig. 82.1).[17] Furthermore, RAG and Artemis deficiencies cause a later block in T-cell development compared with the majority of genetic defects associated with B^+ SCID. This may lead to a stronger competition between donor-derived and autologous T-cell progenitors in patients with B^- SCID who receive unconditioned HSCT.

Finally, in a series of 106 patients with SCID caused by adenosine deaminase deficiency (ADA^- SCID), unconditioned transplantation from MMRDs was associated with a high risk of graft failure.[18]

CLINICAL PEARLS

Outcome of Hematopoietic Stem Cell Transplantation (HSCT) for Primary Immunodeficiencies

For severe combined immunodeficiency (SCID), the 5-year survival rate of patients transplanted between 2000 and 2009 is over 74% and is higher (97%) for patients who receive transplant from matched sibling donors.

Improvements in clinical care (both in critical care and in prevention and treatment of infections) have also contributed to the improved outcome of HSCT for SCID, including transplantation from matched unrelated donors (MUDs). However, the decision to attempt a MUD transplantation for SCID must be weighed against the risks associated with the time interval required to identify such a donor.

Factors influencing survival after transplantation for SCID include younger age at transplant and lack of active infections at the time of transplantation.

The decline of T-cell function that is observed at 10 years or more after transplantation remains a concern and may cause clinical problems. Therefore there is a need for improvements in the procedures used to facilitate and sustain stem cell engraftment and/or to boost donor-derived immunity.

For primary immunodeficiencies other than SCID, there has been a progressive improvement in the outcome following stem cell transplantation. In particular, results are good both for human leukocyte antigen–identical transplants (with a survival rate of 70% or more, depending on the disease) and for MUD or cord blood transplantations. Reduced-intensity conditioning regimens have been often used in these patients, in the attempt to reduce the risks of drug-related toxicity.

Complications Following HSCT for SCID

Despite advances in prophylaxis and treatment, infections (especially those caused by viruses) remain a significant cause of death after HSCT for SCID. In a report of 166 transplantations performed at their center, Buckley et al.[18a] indicated that viral infections accounted for 30 of the 40 deaths observed. CMV and adenovirus were responsible for nine deaths each, and 18 additional deaths resulted from infections caused by EBV, enteroviruses, parainfluenza virus type 3, varicella virus, herpes simplex virus, and respiratory syncytial virus. In a series of 240 patients with SCID who received HSCT in North America between 2000 and 2009, infections accounted for 24 of 62 deaths.[2]

Viral and opportunistic infections are more common early after HSCT, especially in recipients of T cell–depleted haploidentical HSCT, because of the delay in achieving immune reconstitution. Incomplete recovery of immune function at 1 year after

HSCT is associated with a higher risk of late infections. In a single-center study of 90 patients with SCID treated with HSCT, 11 (12%) developed significant infectious complications 2–17 years after transplantation.[19] Among late infections, chronic skin warts caused by papilloma virus have been observed in a significant fraction of infants with γc or JAK3 deficiency after HSCT.[19] This complication may occur also in patients who attain robust immune function and probably results from signaling defects that involve extrahematopoietic cells, such as keratinocytes.

GvHD is another major complication of HSCT for SCID. In a series of 240 patients with SCID who received HSCT in North America between 2000 and 2009, the cumulative incidence of aGvHD of grade 2–4 at 100 days after transplant was 20%, with no significant difference based on donor type.[2] By contrast, in their article describing the experiences of HSCT for SCID at two centers (Brescia, Italy; and Toronto, Canada), Grunebaum et al. reported that aGvHD developed in four (31%) of 13 patients who received related HLA-identical HSCT, 18 (45%) of 40 patients treated with T cell–depleted haploidentical transplantation, and 30 (73%) of 41 patients receiving MUD HSCT.[6] Buckley et al. reported that GvHD occurred in 45 (30.2%) of 149 patients given T cell–depleted mismatched parental bone marrow, eight (47%) of 17 patients given unfractionated HLA-identical marrow, and four (80%) of five patients given placental blood.[18a] In most cases, GvHD occurred when there was presence of transplacentally acquired T lymphocytes. In most cases in this study, the GvHD observed was mild (grade I or II) and required no treatment; however, 11 patients developed GvHD grade III or IV and required treatment with steroids, cyclosporine, and/or tacrolimus. None of these patients has died since then, but one has developed cGvHD. Although continuous improvement in HLA typing has resulted in a progressively lower incidence of aGvHD in the last decades, these data illustrate the need for careful monitoring of infants treated with other than related HLA-identical HSCT and call for adherence to guidelines on the use of immunosuppression for GvHD prophylaxis after MUD HSCT or after conditioned T cell–depleted haploidentical transplantation.

Chronic GvHD disease has been reported in 10 (11%) of 90 patients who have survived for at least 2 years after receiving HSCT for SCID in Paris. Six of them developed disseminated cGvHD, and three died of cGvHD and related infectious complications.[19] A similar rate of cGvHD (15% at 2 years post-HSCT) has been observed in the North American series of 240 infants with SCID.[2]

Immune dysregulation and autoimmunity represent additional complications of HSCT for SCID. In a joint series of 94 infants with SCID who received transplantations in Brescia (Italy) and Toronto (Canada), we have reported that six of 41 patients who received MUD HSCT, and five of 40 children treated with T cell–depleted haploidentical transplantation developed autoimmune cytopenias.[6] These complications may develop a few months after HSCT (when skewing of the T-cell repertoire may be observed) or may persist, particularly in infants with delayed and incomplete immune reconstitution. In particular, Neven et al. have reported that among 90 long-term survivors after HSCT for SCID, 12 patients suffered from autoimmune and inflammatory complications at more than 2 years after HSCT for SCID, and in six of them, the onset of such complications was within the first 2 years after transplantation.[19] These late manifestations of immune dysregulation are often associated with incomplete immune reconstitution and may lead to a poor outcome.

Finally, prolonged nutritional support has been reported after HSCT for SCID. This complication is more frequent among patients treated by mismatched related or unrelated donor HSCT, especially if cGvHD, immune dysregulation, and poor immune reconstitution are also present. Infants with Artemis deficiency (leading to impaired DNA repair) are at particularly high risk for late complications, including growth retardation, requirement for nutritional support, and dental abnormalities.[16,19]

Quality and Kinetics of T-Cell Immune Reconstitution

The effectiveness of HSCT in SCID is well illustrated by the normalization of the number and function of T lymphocytes that is achieved after transplantation (Figs. 82.4 and 82.5). The efficacy of the procedure has been demonstrated in all forms of SCID, although the T-lymphocyte count after HSCT tends to be lower in patients with adenosine deaminase (ADA) deficiency, possibly reflecting irreversible thymic damage. Moreover, normalization of T-lymphocyte count after HSCT demonstrates the ability of stem cells to seed and differentiate in a vestigial thymus.

The kinetics of T-lymphocyte reconstitution differs substantially, depending on the type of transplant. The unmanipulated graft from a related HLA-identical donor contains mature T lymphocytes. Homeostatic as well as antigen-driven expansion of these mature T cells occurs as early as 2 weeks after transplantation (Fig. 82.6).[1] These T cells have a memory (CD45RO) phenotype, are fully competent, and, in fact, provide the recipient with functional immunity.

Mature T cells are present also in bone marrow grafts collected from MUDs. However, the use of conditioning in MUD HSCT impairs, at least in part, immune development in such transplants, compared with unconditioned HSCT from related HLA-identical donors (see Fig. 82.6).

In contrast, newly generated, naïve ($CD45RA^+$ $CD31^+$) T lymphocytes do not appear in circulation until 3–6 months after HSCT, irrespective of the type of transplant (HLA-identical or mismatched), and their number tends to peak at approximately 1 year after HSCT, when a fully polyclonal T-cell repertoire is usually observed. These naïve T lymphocytes are the product of ongoing active thymopoiesis, as shown by the fact that they contain T-cell receptor excision circles (TRECs). TRECs are extrachromosomal DNA episomes, which are generated during V(D)J recombination (Chapter 4) and are not duplicated during mitosis. Therefore TRECs identify newly generated naïve T lymphocytes, and their enumeration in peripheral blood is used as a method to identify babies with SCID at birth.[20]

The kinetics of T-cell reconstitution is influenced by the recipient's age. Transplantations performed early in life (at <3.5 months of age) lead to superior thymic output.[2] This may reflect lack of thymic damage (which is often observed in older infants after infections); alternatively, it is possible that a younger thymus has intrinsic superior ability to support active thymopoiesis.

Quantitation of TRECs sequentially after HSCT is an accepted approach to assess engraftment of *bona fide* stem cells and to monitor persistence of immunity. Although an earlier study had shown that levels of TRECs tended to decline at 10 years after HSCT in recipients of unconditioned mismatched-related transplants, more recent observations from the same group indicate that robust thymopoiesis and generation of a diversified repertoire of T lymphocytes were maintained over the long term after HSCT.[21]

Vigor of immune reconstitution at >2 years after HSCT is influenced by the donor type, use of conditioning, and SCID

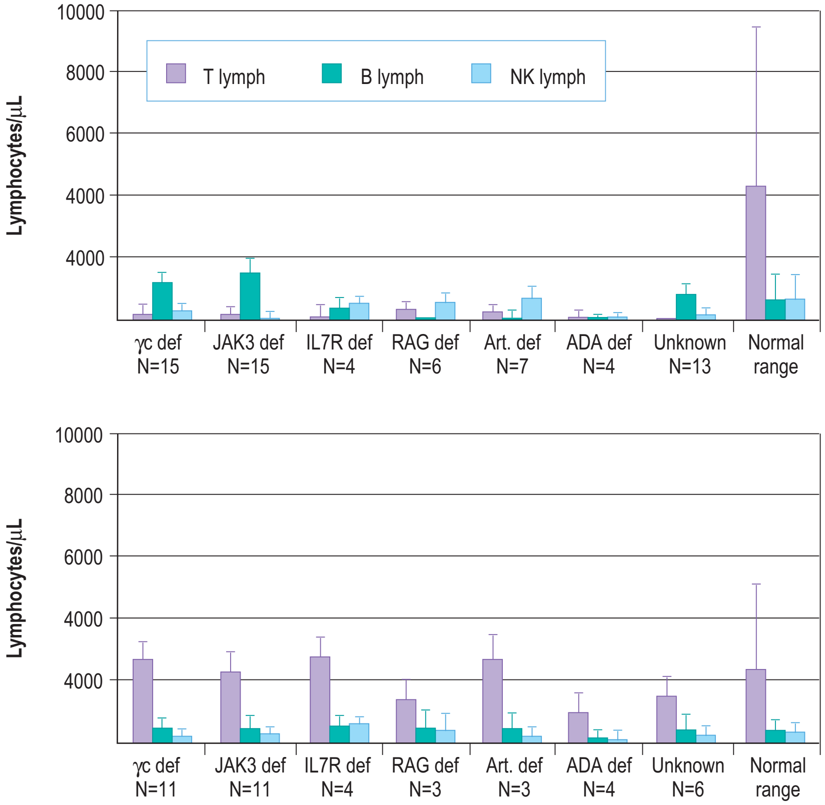

FIG 82.4 Mean (±SE) numbers of $CD3^+$ T cells, $CD19^+$ B cells, and $CD16^+$ natural killer cells before transplantation (A) and at the most recent evaluation after transplantation (B) performed at the University of Brescia, Italy, according to the type of severe combined immunodeficiency (SCID).

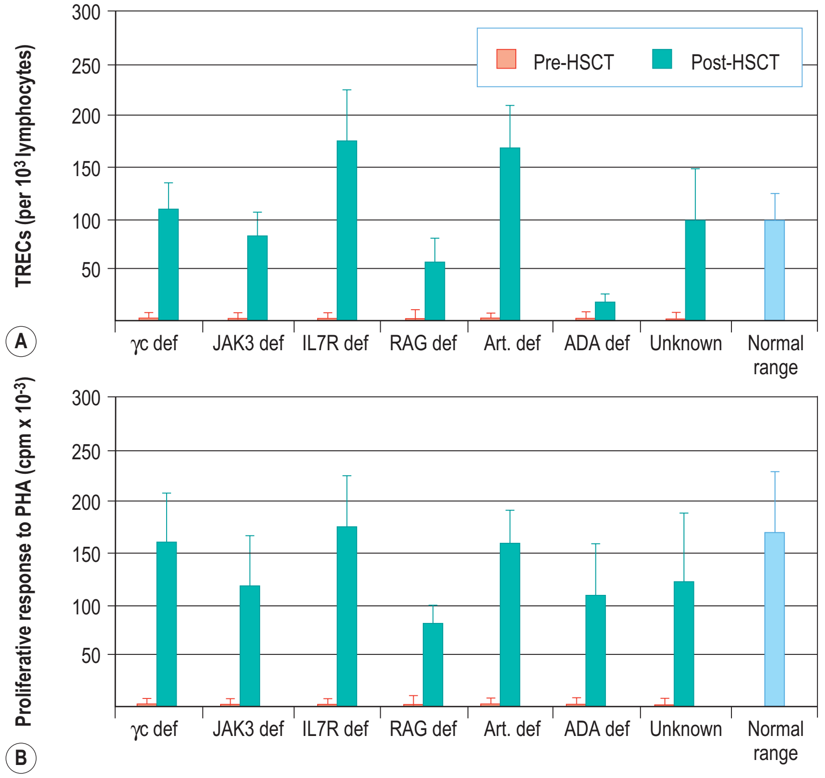

FIG 82.5 Number of T-cell receptor excision circles (TRECs) (A) and *in vitro* proliferative response to phytohemagglutinin (PHA) (B) before transplantation and at the last follow-up after transplantation in a series of 42 infants with severe combined immunodeficiency (SCID) treated at the University of Brescia, Italy, according to the type of SCID.

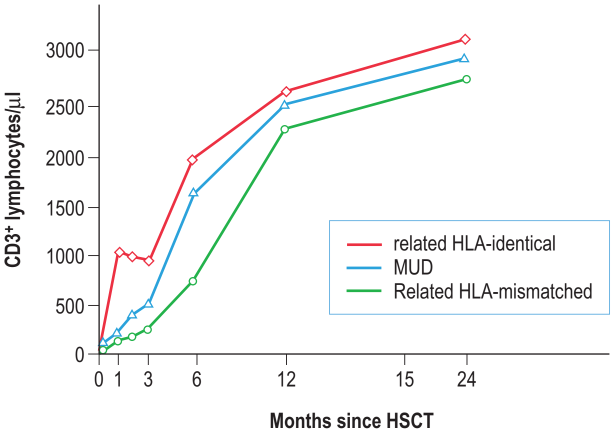

FIG 82.6 Kinetics of CD3$^+$ T lymphocytes reconstitution in 48 infants with severe combined immunodeficiency (SCID) following human leukocyte antigen (HLA)-identical (n = 12), matched unrelated donor (MUD) (n = 15) or haploidentical (n = 21) hematopoietic stem cell transplantation (HSCT), performed at the University of Brescia, Italy. Geometrical mean CD3$^+$ T-cell counts are shown.

phenotype. In particular, in a large series of patients with SCID who received HSCT in North America between 2000 and 2009, higher counts of CD3 cells at 2–5 years after transplantation were associated with HSCT from MSDs, use of conditioning, and B$^+$ or NK$^-$ SCID phenotype.[2] Use of conditioning resulted also in a higher count of naïve CD4 cells.[2]

Reconstitution of B- and NK-Cell Immunity

In contrast to what is observed for T lymphocytes, the engraftment of B cells after HSCT for SCID is often problematic and delayed.

In their series, Buckley et al. reported that only five of 17 survivors of HLA-identical HSCT and 33 of 109 survivors of unconditioned haploidentical HSCT had evidence of donor-derived B lymphocytes; overall, 63 of 126 survivors required intravenous immunoglobulins.[18a] Booster transplants have been used to overcome these problems; 33 of 49 patients who received such booster transplants at Buckley et al.'s institution were reported to be alive with improved immune function.[18a]

In Europe, use of pretransplantation conditioning has been advocated in haploidentical HSCT with the goal of facilitating engraftment of stem cells and thus also of B lymphocytes. Mazzolari et al. have reported that donor B-cell engraftment was achieved in only one of 11 survivors after unconditioned HSCT compared with 26 of 29 patients who received a myeloablative conditioning regimen.[22]

Recently, higher B-cell counts and a better chance of attaining independence from Ig replacement therapy in recipients of conditioned HSCT for SCID have been confirmed also in a large North American study.[2] Finally, attainment of normal B-cell function may also depend on the nature of the genetic defect, as shown by the fact that among infants with B$^+$ SCID, those who have an *IL-7RA* gene defect usually develop normal B-cell immunity after HSCT, even if no donor-derived B cells are present, whereas patients with γc or JAK3 deficiency (both of which compromise B-cell function) often remain dependent on Ig substitution therapy if engraftment of donor-derived B cells is not achieved. This reflects the importance of interleukin-21 (IL-21)–mediated, γc/JAK3-dependent signaling for germinal-center reaction, plasma-cell differentiation, and antibody production.

More limited data are available about reconstitution of NK cell function. In patients with NK$^-$ SCID, NK cells are often the first cells to appear after haploidentical HSCT. Lower NK-cell counts are observed at long-term follow-up after HSCT in patients with γc or JAK3 defects.

HSCT for Combined Immunodeficiencies Other Than SCID

The Primary Immune Deficiency Treatment Consortium (PIDTC) has established criteria to distinguish typical SCID from other forms of combined immunodeficiency characterized by residual (although lower than normal) T cell–mediated immunity.[23] Omenn syndrome is a fatal disorder, unless treated with HSCT. Satisfactory results have been obtained with transplantation from related HLA-identical donors, but less so from haploidentical donors. However, an improved outcome has been observed in the last 15 years. Mazzolari et al. have reported that 9 of 11 patients with Omenn syndrome were alive after HSCT; importantly, of these, only one had a matched sibling, whereas two infants had a phenotypically identical related donor, three were treated with MUD HSCT, and five received a haploidentical HSCT.[22]

HSCT has been attempted also in other predominant T-cell immunodeficiencies, such as purine nucleoside phosphorylase deficiency, cartilage hair hypoplasia, and other forms of T-cell activation deficiency. Overall, survival after HSCT for these disorders is worse than in typical SCID (approximately 50%).[1]

Major histocompatibility complex (MHC) class II deficiency remains a very difficult disease to treat with transplantation. In the European series, cumulative survival after HSCT performed in 1995–2005 was around 40%.[1] Many patients with this deficiency fail to reconstitute the number of circulating CD4 T lymphocytes, probably because the lack of expression of HLA class II molecules on thymic epithelial cells prevents positive selection of CD4 lymphocytes.

The mainstay of treatment for patients with complete DiGeorge syndrome is represented by thymic transplantation.[24] However, HSCT or even transplantation of unmobilized peripheral blood mononuclear cells may be attempted if an HLA-identical donor is available; in such cases, immune reconstitution is provided by mature T lymphocytes contained in the graft.

Patients with CD40 ligand (CD40L) deficiency suffer from recurrent bacterial and opportunistic (*Pneumocystis jiroveci, Cryptosporidium parvum*) infections, resulting in increased mortality in childhood and young adulthood. This has prompted use of HSCT in the treatment of this disease. In a series of 38 patients transplanted in Europe, 26 (68.4%) survived.[25] Early age at transplantation and lack of preexisting pulmonary disease were associated with a more favorable outcome. Successful outcome has been also reported after HSCT for CD40 deficiency.

X-linked immunodeficiency with ectodermal dystrophy, caused by mutations of the *IKBKG* (*NEMO*) gene that impair nuclear factor (NF)-κB signaling, may also present with features of combined immunodeficiency. Colitis is also frequently seen and may be caused by immune dysregulation as well as abnormalities of NF-κB signaling in the gut epithelial cells. Initial observations supported the notion that use of myeloablative regimens for HSCT is poorly tolerated in this condition, also because of increased mucosal toxicity. However, graft failure has been observed when using reduced-intensity conditioning, and in contrast, several patients have tolerated myeloablative regimens well and have attained immune reconstitution.[26] Yet, persistence of the colitis after HSCT has been reported in a proportion of the patients.[27] Conflicting results have also been reported after

HSCT in patients with hypermorphic mutations of the *IKBA* gene, another cause of combined immune deficiency with ectodermal dystrophy.[28]

Wiskott-Aldrich Syndrome

Bone marrow transplantation for correction of WAS was attempted as early as 1968, with partial success. Full correction following HSCT was first reported in 1978 when a more robust conditioning regimen was used. Since then, results of related HLA-identical HSCT in WAS have been consistently good, with continuous improvement in recent years, and excellent results have been also achieved with HSCT from MUDs. A multiinstitutional study of 194 patients with WAS treated with HSCT showed an overall survival of 84%, and a 5-year survival as high as 89.1% for transplantations performed since year 2000.[29] For patients treated with MUD HSCT, younger age (<5 years) at transplantation was associated with an improved outcome. Patients with preexisting autoimmunity or recurrent/severe infections had a higher rate of complications after transplantation. Mixed chimerism was associated with the presence of immunological abnormalities and increased risk of autoimmunity, and myeloid chimerism <50% was associated with persistent thrombocytopenia.[29] Use of a conditioning regimen other than fully myeloablative conditioning was associated with reduced disease-free survival in another study of 14 patients.[30]

Cytotoxicity Defects

Familial hemophagocytic lymphohistiocytosis (FHL) comprises a genetically heterogeneous group of disorders of T cell– and NK cell–mediated cytotoxicity. Although chemotherapy may induce remission, patients with FHL tend to relapse and ultimately die, mostly as a result of multiorgan failure observed in the accelerated phase of the disease. At present, HSCT is the only curative approach to FHL. However, patients with FHL often are critically ill, with extensive organ involvement and/or active infections, and may suffer from refractory disease. For these reasons, patients are unusually prone to developing transplantation-related toxicities and complications. Recently, significantly improved outcomes with increased survival have been reported after HSCT with the use of a reduced-intensity conditioning regimen.[31] However, use of reduced-intensity conditioning is associated with a higher risk of mixed and recipient chimerism (65%), even for HSCT from matched donors.[31] Selection of optimal family donors is an important issue for HSCT in FHL. Functional and genetic studies should be used to screen potential family donors to avoid obtaining transplants from genetically affected but as-yet asymptomatic subjects.

Excellent results have been reported also after HSCT for X-linked lymphoproliferative disease type 1 (XLP1). In an international series of 91 patients with XLP caused by a *SH2D1A* gene defect, survival was 81.4% in 43 patients treated with HSCT compared with 62.5% in 48 untransplanted patients.[32] Furthermore, the majority of untransplanted survivors required Ig replacement therapy, whereas good immune reconstitution was achieved in most transplanted patients. However, survival was poorer (50%) among patients with a previous history of hemophagocytic lymphohistiocytosis (HLH), suggesting that ideally the transplantation should be performed before onset of EBV infection.[32] More recently, a single-center experience involving 16 patients with XLP1 showed that reduced-intensity conditioning with alemtuzumab, fludarabine, and melphalan is effective even in patients with XLP1 with a history of HLH (Fig. 82.7).[33] Survival was 80% at 1 year and 71% in the long term; mixed chimerism was common but, in most cases, was sufficient to control the disease. Infectious complications (especially viral infections) were recorded in the majority of the patients.[33]

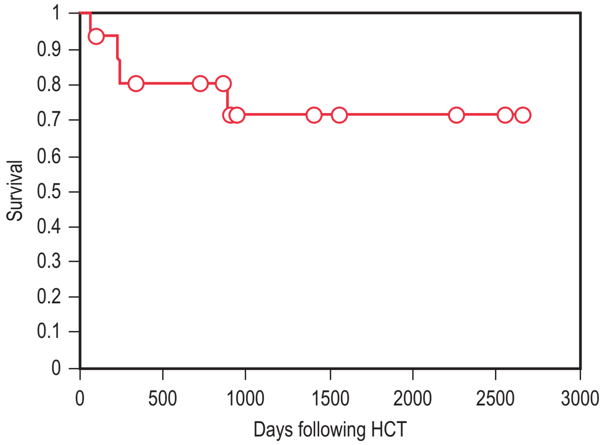

FIG 82.7 Long-term survival of patients after reduced intensity conditioning hematopoietic stem cell transplantation (HSCT) for X-linked lymphoproliferative disease type 1 (XLP1). (With permission from Moratto D, Giliani S, Bonfim C, et al. Long-term outcome and lineage-specific chimerism in 194 Wiskott–Aldrich Syndrome patients treated by hematopoietic cell transplantation between 1980–2009: an international collaborative study. Blood 2011;118:1675–84.)

XLP type 2 (XLP2), caused by mutations in the X-linked inhibitor of apoptosis (*XIAP*) gene, is associated with various phenotypes, including XLP, HLH, and severe colitis. An international survey of transplantation for this condition identified 19 patients who underwent HSCT, in which fully myeloablative (n = 7), reduced-intensity (n = 11), or intermediate-level (n = 1) conditioning was used.[34] Myeloablative conditioning was associated with poor survival (14%) and a high rate of serious, transplantation-related toxicities. Survival was better (55%) in patients who received reduced-intensity conditioning and was especially good (86%) in those in remission from HLH.[34]

The hematological and immune complications of Chediak-Higashi syndrome (CHS) can be cured with bone marrow transplantation. In a series of 35 patients, 5-year survival after HSCT was 62%.[35] Mortality was higher in patients who were in the life-threatening accelerated phase of the disease at the time of transplantation and in those who received HSCT from an alternative related donor.[35] Use of MUDs represents a valid option for HSCT in patients with CHS. However, the long-term outcome of patients with CHS treated with HSCT remains unclear, especially since neurological deterioration has been consistently observed several years after transplantation.

Griscelli syndrome type 2 (GS2) is a genetic disease characterized by hemophagocytic lymphohistiocytosis and a high risk of neurological complications. Correction of the cytotoxicity defect after HSCT has been reported in a small series of patients with GS2, but neurological sequelae remain a challenge and may develop even in patients without preexisting neurological problems.[36]

Phagocytic Cell Disorders

Although regular administration of prophylactic antibiotics and antifungal agents (with the possible addition of interferon [IFN]-γ) has clearly improved the outcome in patients with CGD, this remains a severe disorder with a rather high risk of complications and death, especially in patients with oxidase-null phenotype.[37] Therefore there has been a renewed interest in HSCT for CGD. In a survey of the European experience in 1985–2000, 27 patients with CGD were treated with HSCT; most of them received unmodified bone marrow from an HLA-identical sibling after myeloablative conditioning. Overall, 23 of the 27 patients were reported to have survived, and the disease had been cured in 22 of them.[38] In this study, all 18 patients who were infection-free at the time of transplantation survived. However, a real breakthrough in the treatment of CGD was provided by a prospective multicenter study in 56 patients with CGD, 42 of whom had high-risk features, including treatment-refractory infections and severe inflammatory complications.[39] In this study, reduced-intensity conditioning (with low-dose or targeted busulfan administration, high-dose fludarabine, and serotherapy) and transplantation from matched related (n = 21) or unrelated (n = 35) donors resulted in a 2-year overall survival rate of 96% and an event-free survival rate of 91% (Fig. 82.8). Stable (≥90%) myeloid chimerism was documented in 93% of surviving patients. A low rate of aGvHD of grade III/IV (4%) and of cGvHD (7%) was observed.

HSCT is a successful and lifesaving procedure also in patients with the complete form of leukocyte adhesion defect type 1 (LAD-1). A multicenter study of 36 such patients who underwent HSCT between 1993 and 2007 reported an overall survival of 75%, with similar results when matched related or unrelated donors were used. Mortality was higher (four of eight cases) after haploidentical HSCT. Stable mixed multilineage chimerism is sufficient to cure the disease.[40] More recently, employing blockade of the P40 subunit of IL-23 and IL-12 with ustekinumab has been reported resolve inflammatory symptoms in a patient with LAD-1 after 1 year of therapy.[40a]

Administration of recombinant G-CSF is the treatment of choice for patients with severe congenital neutropenia (SCN). However, a subgroup of these patients fail to respond to G-CSF, and some of them are at high risk for development of myelogenous leukemia. A retrospective multicenter study of 136 patients with SCN who underwent allogeneic HSCT between 1990 and 2012 reported a 3-year overall survival rate of 82%, with 17% transplantation-related mortality.[41] Transplantation at a younger age (<10 years) and use of matched related or unrelated donors were associated with an improved outcome.

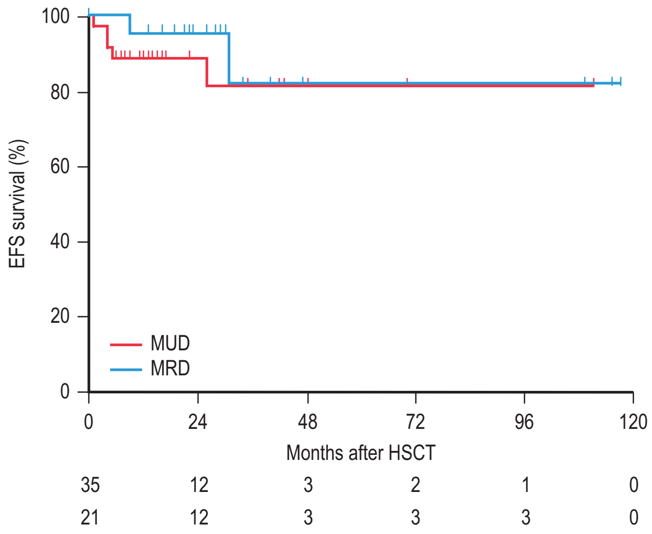

FIG 82.8 Event-free survival (EFS) in patients with chronic granulomatous disease (CGD) after reduced-intensity conditioning hematopoietic stem cell transplantation (HSCT) from matched related donors (MRD) or matched unrelated donors (MUD). (With permission from Eapen M, DeLaat CA, Baker KS, et al. Hematopoietic cell transplantation for Chediak-Higashi syndrome. Bone Marrow Transplant 2007;39:411–5.)

Other Primary Immune Deficiencies

IFN-γ receptor 1 deficiency leads to severe mycobacterial infections, with a high rate of mortality early in life. Although HSCT should theoretically correct the disease, results have been disappointing, with few exceptions. An international survey of eight transplanted patients showed that only two were in full remission 5 years after transplantation. The high level of IFN-γ in these patients inhibits engraftment of donor-derived HSCs, accounting for the high rejection rate. Correction of the disease has been reported with HSCT following control of mycobacterial infection, normalization of IFN-γ levels, and use of myeloablative conditioning.

Immunodysregulation/polyendocrinopathy/enteropathy/X-linked (IPEX) syndrome is a severe disorder with immune dysregulation caused by mutations of the *FOXP3* gene, which plays a critical role in the development and function of regulatory T cells (Tregs). Patients with IPEX often die early in infancy. HSCT is the only curative approach to treat this disease.[42] Selective advantage for donor-derived Tregs has been observed in patients with mixed chimerism after HSCT.[43] However, other studies have reported a higher risk of graft failure and increased occurrence of posttransplantation autoimmune cytopenias following HSCT with reduced-intensity conditioning.[44]

Dedicator of cytokinesis 8 (DOCK8) deficiency is a recently described form of combined immunodeficiency with elevated serum IgE, cutaneous viral infections, and a high risk of malignancy. HSCT represents an effective form of treatment for this disease. In a series of 11 patients, seven of whom received HSCT from related donors and four from unrelated donors, survival was excellent (91%), and selective advantage for donor-derived T cells and switched memory cells was noticed.[45] In other studies, successful outcomes were reported with either myeloablative or reduced-intensity conditioning. HSCT has been also successfully used in patients with combined immune deficiency resulting from DOCK2 deficiency.[46]

FUTURE TRANSLATIONAL RESEARCH FOR HCST IN THE TREATMENT OF PID

Although HSCT has clearly shown its efficacy in patients with severe forms of PID, several goals remain to be met. In particular, the main areas of interest for future development include *(i)* methods to improve and sustain engraftment of stem cells; *(ii)* strategies to facilitate engraftment and to reduce the incidence of GvHD in recipients of mismatched or matched unrelated transplants; *(iii)* attempts to improve thymopoiesis, with the goal to accelerate immune reconstitution and to avoid or postpone long-term decline of immunity; and *(iv)* design strategies to reduce the burden of infections after HSCT.

Generation of a diversified pool of naïve T lymphocytes after HSCT depends on thymic function. Use of cytotoxic drugs and GvHD are significant risk factors for posttransplantation T-cell deficiency as they interfere with normal thymic function.[47] Use of mAbs against CD117 (c-kit) has been proposed to displace autologous stem cells and favor engraftment of donor-derived cells, while avoiding the drug-related toxicity of chemotherapy and radiotherapy.[48] Recognition that B-cell engraftment after HSCT is hampered by competition between host and donor early B-cell precursors[49] may prompt novel forms of conditioning regimens targeted to host pro-B lymphocytes, in an attempt to facilitate development of donor-derived B cells, even in the unconditioned HLA-identical setting.

Strategies aimed at improving thymic function after HSCT may include *(i)* protection of thymic stroma that supports thymopoiesis and *(ii)* direct stimulation of early T-cell progenitors. Keratinocyte growth factor (KGF) is potentially attractive because it protects the thymic stroma. Administration of KGF before HSCT has been shown to enhance thymopoiesis and peripheral T-cell numbers and to reduce the incidence and severity of GvHD in murine models of HSCT.[50] However, more must be learned about the long-term outcome of this treatment before clinical trials can be started.

Attempts to accelerate immune reconstitution might be based on the use of cytokines, such as IL-7, which promote T-cell development and maturation in the thymus. However, experience in severely immunodeficient mice has shown that infusion of IL-7 provides limited benefit in the MHC-compatible or partially compatible setting, whereas it has facilitated T-cell development in a fully mismatched setting.

Finally, besides use of virus-specific CTLs,[14] infusion of donor T cells that have antiinfective activity but no GvHD activity might help reduce infection-related mortality after HSCT. Such strategy could be based on removal of alloreactive cells by negative selection using anti-CD25 or anti-CD69 antibodies.

ON THE HORIZON

The following strategies may help improve even further the outcome of hematopoietic stem cell transplantation (HSCT) for primary immunodeficiency (PID) in the future:

Methods to improve and sustain engraftment of stem cells

Strategies to facilitate engraftment and reduce the occurrence of graft-versus-host disease (GvHD) in patients with mismatched or matched unrelated donor (MUD) transplant

Approaches to increase thymopoiesis and accelerate immune reconstitution

Design of therapeutic strategies to reduce the infectious complications of HSCT

MULTIPLE-CHOICE QUESTIONS

1. What distinguishes the kinetics of immune reconstitution following hematopoietic stem cell transplantation (HSCT) with unmanipulated bone marrow from a matched sibling donor versus a T cell–depleted transplantation from a haploidentical donor in an infant with severe combined immunodeficiency (SCID)?
   A. Transplantation from a matched sibling donor will provide rapid engraftment of B lymphocytes.
   B. Transplantation from an human leukocyte antigen (HLA)–matched donor allows rapid T-cell engraftment.
   C. Only transplantation from a matched sibling donor permits durable T-cell reconstitution.
   D. Transplantation from an HLA-matched donor allows rapid multilineage hematopoietic engraftment.
   E. There are no differences in the kinetics of immune reconstitution.

2. Which of the following factors negatively affect outcome of HSCT for SCID?
   A. B^+ SCID phenotype
   B. History of previous infections
   C. Presence of active infections at the time of transplantation
   D. Age younger than 2 months of life
   E. Transplantation from a haploidentical donor

3. Use of reduced intensity conditioning regimens may reduce drug-related toxicity but often results in mixed chimerism after HSCT for primary immune deficiency (PID). In many cases, mixed chimerism is sufficient to control the disease phenotype, but in some forms of PID, it is associated with an increased risk of complications. Can you identify in which of the following immunodeficiency this is the case?
   A. Familial hemophagocytic lymphohistiocytosis (FHL)
   B. Chronic granulomatous disease (CGD)
   C. Immune dysfunction/polyendocrinopathy/enteropathy/X-linked (IPEX) syndrome
   D. Wiskott-Aldrich syndrome (WAS)
   E. Leukocyte adhesion defect type 1 (LAD-1)

Hematopoietic Stem Cell Transplantation for Malignant Diseases

Pashna N. Munshi, Scott D. Rowley, Robert Korngold

Hematopoietic stem cell transplantation (HSCT) is effective treatment for most hematological malignancies, including leukemia, lymphoma, multiple myeloma (MM), and clonal myelodysplastic and myeloproliferative diseases (MPDs), as well as nonmalignant diseases, such as autoimmune disorders and hemoglobinopathies. Autologous HSCT (auto-HSCT) is commonly used as therapy for patients with malignancies sensitive to chemotherapy or radiotherapy in a dose-responsive manner. These patients receive intensive cytoreductive regimens designed to eliminate all tumor cells but which, in so doing, also destroy the patient's hematopoietic function needed for blood formation. Infusion of previously collected hematopoietic stem cells (HSCs) will rescue the patient from the marrow-ablative effects of this treatment. Allogeneic HSCT (allo-HSCT), in addition to reconstitution of bone marrow function, achieves an immunotherapeutic benefit from the donor natural killer (NK) and T cells infused into the graft attacking residual tumor cells that persist after the conditioning regimen, thereby greatly reducing the risk of later relapse of the disease. Thus allo-HSCT, in contrast to auto-HSCT, does not require administration of dose-intensive regimens to achieve complete tumor cell kill, and nonmyeloablative regimens may be used to "condition" the host for transplantation.

Auto-HSCT (including syngeneic twins) is justified by the dose-sensitivity of most hematological malignancies. Although there is some evidence that a more robust immunological recovery after auto-HSCT predicts for a lower risk of relapse, possibly opening an area of research in graft (or host) modification to enhance such recovery, treatment of the disease is primarily a result of the dose-intensive, myeloablative chemotherapy or radiotherapy administered. Infusion of cells is only required to recover hematopoiesis, and the stem cell infusion is, therefore, intended to treat the deleterious effect of chemotherapy on bone marrow function and not the disease itself. The primary complications of auto-HSCT result from the administration of a dose-intensive regimen and include a period of marrow hypoplasia, possibly requiring blood transfusions and antibiotics. Nonhematological toxicities, including mucositis resulting in inanition and diarrhea, and damage to other organs, such as the lung, liver, and kidney, limit the amount of chemotherapy that can be administered. Currently, the treatment-related mortality risk for most treatment regimens is ≤5%. Relapse of disease, particularly for patients who come to transplantation with chemotherapy-refractory disease, is the primary cause of failure of auto-HSCT. Improvements in the outcome of auto-HSCT will require new conditioning regimens with greater tumor cell kill, effective posttransplantation consolidation therapies, or strategies (*e.g.*, tumor vaccines) to induce an effective immune responsiveness to the residual disease after transplantation.

THERAPEUTIC PRINCIPLES

Autologous and Allogenic Transplantation

Autologous Transplantation

- Based on chemotherapy or radiotherapy dose-sensitivity of disease being treated
- Requires collection and storage of adequate hematopoietic stem cells (HSCs), preferably before extensive alkylating agent or purine analogue therapy
- Lower risk of graft failure (no immunological rejection)
- No routine posttransplantation immunosuppression
- Minimal risk of graft-versus-host disease (GvHD)
- No graft-versus-tumor (GvT) effect
- More rapid posttransplantation immune reconstitution
- Risk of tumor cell contamination in HSC product
- Not useful for diseases in which normal HSCs cannot be collected (*e.g.*, chronic myelogenous leukemia, myelodysplasia)

Allogeneic Transplantation

- Rescues bone marrow function after dose-intensive therapy
- Effective with reduced-intensity conditioning regimens
- Achieves a GvT effect in many malignancies
- Risk of GvHD distinct from the beneficial GvT effect
- Higher risk of transplantation-related complications that may offset the benefit of the GvT effect
- Risk of immunological graft rejection
- Slow posttransplantation immune reconstitution
- No risk of tumor-cell contamination with healthy donor

Allo-HSCT has a much lower relapse risk compared with auto-HSCT as a result of a beneficial immunological graft-versus-tumor (GvT) effect achieved by engraftment of the donor immune system. Allograft recipients, however, face a much higher risk of treatment-related mortality (TRM) from the detrimental immunological GvH response against healthy tissues of the patient. The principal complication of allo-HSCT is graft-versus-host disease (GvHD), which can occur early (acute GvHD, within the first several weeks) (Table 83.1) or late (chronic GvHD, months to several years) after transplantation. The rate of overall incidence of moderate to severe acute GvHD (aGvHD) is 35%–80% for all patients receiving a human leukocyte antigen (HLA)–matched related or unrelated donor stem cell transplant, and aGvHD is a primary cause of death in 10–20% of these patients. Chronic GvHD (cGvHD), a clinicopathologically distinctive form of this

TABLE 83.1 Acute Graft-Versus-Host Disease (GvHD)

Clinical Staging

Stage	Skin	Liver	Gut
1	Maculopapular rash <25% BSA	Bilirubin 2–3 mg/dL	Diarrhea 500–1000 mL/day, or Persistent nausea
2	Maculopapular rash 25–50% BSA	Bilirubin 3–6 mg/dL	Diarrhea 1000–1500 mL/day
3	Generalized erythroderma	Bilirubin 6–15 mg/dL	Diarrhea >1500 mL/day
4	Desquamation and bullae formation	Bilirubin >15 mg/dL	Pain ± ileus

Clinical Grading

Overall Grade	Skin	Liver	Gut	Functional Impairment
0 (none)	0	0	0	0
1 (mild)	1–2	0	0	0
2 (moderate)	1–3	1	1	1
3 (severe)	2–3	2–3	2–3	2
4 (life-threatening)	1–4	1–4	1–4	3

Adapted from: Harris AC, Young R, Devine S, et al. International, Multicenter Standardization of Acute Graft-versus-Host Disease Clinical Data collection: A Report from the Mount Sinai Acute GVHD International Consortium. Biol Blood Marrow Transplant 2016;22:4–10.

alloreaction, occurs in up to 80% of recipients, may involve aspects of regulatory T cell (Treg) dysfunction and autoimmune-like responses, and may require years of therapy before tolerance is achieved allowing withdrawal of immunosuppressant medications. Other significant complications of allo-HSCT relate to problems of inadequate reconstitution of the immune system of the patient and the concomitant risk of opportunistic infections, including viral and fungal infections that are rarely observed in healthy hosts. Despite the apparent risks associated with allo-HSCT, this treatment holds great promise as a curative therapy for several tumor types, particularly with strategies either to enhance the efficacy of the GvT effect or decrease the toxicity of the graft-versus-host (GvH) response. Efforts have been made in recent years to make HSCT less toxic by development of low-dose, nonmyeloablative conditioning regimens that allow the treatment of older patients or those with comorbid health issues that otherwise preclude treatment with high doses of chemotherapy.[1]

IMMUNE MECHANISMS RELATED TO ALLO-HSCT

Histocompatibility

The HLA major histocompatibility complex (MHC; Chapter 5) is the primary consideration in the selection of a donor for allo-HSCT, since its loci contribute significantly to host-versus-graft (HvG), leading to immunological rejection of donor HSC, and to GvH (leading to GvHD and GvT) reactions. HLA antigens are classified as class I (HLA-A, -B, -C) and class II (HLA-DR, -DQ, -DP) molecules, and typing of donors and patients can be performed using low- or high-resolution techniques. The low-resolution serological techniques can determine a phenotypic mismatch (*e.g.,* A02 vs A03), whereas high-resolution molecular techniques can identify allelic genotypic differences (*e.g.,* A*02:01 vs A*02:02). The risks of aGvHD, cGvHD, and transplantation-related mortality increase with the number of HLA mismatches, and ideally, genotypically matched unrelated donors are sought for patients lacking an HLA-identical sibling. Disparity at HLA-A, -B, -C, and DRB1 alleles are definite risk factors for survival after unrelated donor transplantation, whereas single HLA-DQ or -DP mismatches appear to be better tolerated and/or permissive, meaning they do not have a deleterious impact on clinical outcome.[2]

Not all mismatches result in a deleterious clinical outcome, and identification of permissive mismatches will improve the number of donors available to the patient. Algorithms accounting for possible permissive mismatching in the selection of unrelated donors are currently being developed and tested.[3]

GvHD and GvT occurring after HLA-compatible sibling transplantation demonstrate the importance of minor histocompatibility antigens (miHAs) on the outcome of allo-HSCT. MiHAs are derived from polymorphic sites in normal proteins between individuals and are constantly processed by proteasome activity and presented on the cell surface by MHC molecules; they can thus be recognized by T cells from a HLA-matched donor. As a result, hundreds of miHAs may be variably expressed on host tissues and can trigger an alloresponse from donor T cells, thereby causing GvHD. Unfortunately, only a few miHAs have been identified, such as those on the Y chromosome leading to a higher risk of GvHD in male recipients of cells from female donors; miHA matching of a male donor for a male recipient is not a component of current algorithms for donor selection.

Research in the field of additional criteria for donor selection is ongoing. Human NK cells possess clonally distributed, inhibitory receptors termed "killer cell immunoglobulin-like receptors" (KIRs) that recognize epitopes shared by groups of HLA class I alleles (KIR ligands). KIR–ligand mismatching in the GvH direction appears to result in lower risk of relapse- and nonrelapse-related mortality after allo-HSCT. Activating KIRs transduce signals to activate NK cells, and the presence of these cells is associated with a lower risk of leukemia relapse after unrelated and haploidentical transplantation as well as protection against certain viral infections, such as human immunodeficiency/acquired immunodeficiency syndrome (HIV/AIDS) or hepatitis C virus (HCV) infection. This effect appears to be more evident in haploidentical transplantation and in umbilical cord blood (UCB) transplantation. The benefit of KIR–ligand mismatching is less obvious (and more controversial) in unrelated transplantations and after transplantation with T cell–replete grafts in which the antitumor effects of NK cells may be obscured by GvH reactions mediated by T cells.

Graft-Versus-Host Disease

GvHD is caused by mature donor T cells contaminating the HSC inoculum, which recognize HLA or miHA differences expressed by host antigen-presenting cells (APCs) and tissues (Fig. 83.1).[4] Cytokines released from host cells after a patient has received dose-intensive tumor cytoreductive chemotherapy or radiotherapy conditioning create an inflammatory environment that enables the generation of a response of infused donor T cells against host antigens. This initiates a cascade of T-cell activation events, which results in proliferation, release of additional inflammatory cytokines, and the generation of effector T cells that can infiltrate target tissue, particularly the lymphoid system, intestinal tract, skin, and liver and mediate the destruction of host cells in those organs. Both CD4 and CD8 T cells can be

FIG 83.1 Development of Graft-Versus-Host Disease (GvHD). Cytoreductive preconditioning treatment of patients with hematological malignancies with total body irradiation (TBI) or chemotherapeutic drugs causes damage to epithelium in the skin and gastrointestinal tract and activates the release of inflammatory cytokines by dendritic cells (DCs) and macrophages (Mϕ) in those tissues. These cytokines include tumor necrosis factor-α(TNF-α) and interleukin (IL)-1, which upregulate adhesion molecules and chemokine release in the vascular endothelium of the tissues. Activated DCs also migrate to the lymphoid system, where they can present recipient histocompatibility antigens to infused donor T cells that are in the hematopoietic stem cell (HSC) graft. DCs release IL-12, which helps activate CD4 and CD8 T cells, as well as natural killer (NK) cells. These responding cells proliferate and produce additional inflammatory cytokines, including interferon-γ (IFN-γ), TNF-α, and IL-2. Mϕ are activated by both IFN-γ and lipopolysaccharide (LPS) produced by bacteria found in the intestinal tract, and these cells then produce high levels of more TNF-α. TNF-α has many properties, including direct induction of apoptosis on cells in the tissues of target organs of GvHD, but it also helps effector T cells to home to and enter tissue sites through the vascular endothelium. Effector T cells specific for host histocompatibility antigens then get reactivated and perform their effector functions, including release of inflammatory and cytolytic cytokines and direct killing of recipient-type cells in the lymphoid compartment and in the skin, gut, and liver.

involved in GvHD, depending on the specific class I or class II HLA or miHA disparities involved.

The simplest way to avoid the development of GvHD is to deplete the donor HSC graft of T cells before infusion to a cell dose below 10^5 cells/kg body weight. This approach has succeeded in significantly diminishing the incidence of GvHD, but other complications related to the ensuing delay in immune reconstitution of recipients, an increased risk of relapse from loss of the GvT effect, and a higher rate of engraftment failure (also from loss of the GvH effect) have resulted in inconsistent improvement in long-term survival, compared with T cell–replete products. The conundrum is that the same alloreactive donor T cells that mediate GvHD can also cause a GvT response, although there may also be additional tumor-specific or hematopoietic tissue specific T cells.[5] Thus the overriding goal is to be able to manipulate the donor HSC inoculum in such a way as to avoid GvHD but to still be able to mediate a GvT effect.[6]

KEY CONCEPTS

Graft-Versus-Host Disease (GvHD)

- Caused by donor–recipient differences in:
  - Major histocompatibility complex (MHC) molecules
  - Minor histocompatibility antigens (miHAs)
- Mediated by mature donor CD4 and/or CD8 T cells
- Requires inflammatory cytokines
- Primary target organs include lymphoid system, skin, gastrointestinal tract, and liver
- Acute and chronic forms

Clinical Aspects of aGvHD

Usually developing within the first 3 months after transplantation, aGvHD is a clinical diagnosis with characteristic but nondiagnostic pathological findings, with the most common presenting manifestations including skin rash; nausea, anorexia, and diarrhea; and jaundice, depending on the target organ(s) most affected.[7,8] In addition to the increased risks of developing aGvHD related to the extent of HLA and miHA disparity, additional factors include the advanced age of either the donor or the recipient, gender disparity (female donor–male recipient), donor parity (female donors), and infusion of T cell–replete HSC products. Conditioning with reduced-intensity regimens, with lower regimen-related toxicities to nonhematological tissues, also results in a lower risk of aGvHD and may delay the onset of its initial manifestation. Interactions between microbial-associated molecules and innate immune receptors (*e.g.,* Toll-like receptors [TLRs]) appear to be involved in GvHD pathogenesis, as demonstrated in both murine models and human transplantation. Research has shown an interaction between the host's gut microbiota and immune system.[9] On the basis of this knowledge, experiments to decrease transplantation-related GvHD by altering the gut microbiome are being actively pursued.

Pharmacological agents are the mainstay of aGvHD prophylaxis. Most patients receive a combination of a calcineurin inhibitor (tacrolimus or cyclosporine) along with an antimetabolite, such as methotrexate or mycophenolate mofetil (MMF). Methotrexate is associated with delayed engraftment, mucositis, idiopathic pneumonia syndrome, and other transplantation-related complications, which has prompted the development of other combination regimens, such as a calcineurin inhibitor in combination with sirolimus or MMF, or reduced doses of methotrexate. The addition of antithymocyte globulin (ATG) to the conditioning regimen lowers the incidence of both GvH and HvG reactions because of its persistence for several days after HSC infusion, effectively depleting T cells from the graft as well as the host. However, patients treated with ATG may face higher risks of infectious complications, including Epstein-Barr virus (EBV)–associated posttransplantation lymphoproliferative disorder as a result of the greater immunosuppression achieved. Novel combinations of agents continue to be explored to reduce the cost and morbidity of aGvHD and its treatments.

The administration of high-dose cyclophosphamide, an alkylating agent of the nitrogen mustard family, after transplantation reduces the risks of acute and/or chronic GvHD and is a prime example of drug-induced immunological tolerance, a concept first demonstrated by Schwartz and Dameshek in their experiments using 6-mercaptopurine.[10] Subsequently, in 1963, Berenbaum and Brown demonstrated immune tolerance to skin allografts in adult mice by using cyclophosphamide.[11] Post-transplantation cyclophosphamide given on days 3 and 4 after transplantation is now a standard regimen used in haploidentical allogeneic transplantations in combination with other immunosuppressive drugs and as a single agent in matched unrelated and related transplantations, reducing the complications of graft failure and life-threatening aGvHD associated with transplantation of HLA disparate grafts.[12]

Glucocorticoids with a calcineurin inhibitor remain the standard approach to initial systemic management of clinically significant aGvHD. About 30–50% of patients will respond to initial therapy, and patients who fail to respond have a poor prognosis, as additional agents added for control greatly increase the risk of opportunistic infections and other treatment-related complications. The use of higher doses of corticosteroids, or the addition of ATG, for example, in the initial treatment of aGvHD do not improve patient outcomes and should be reserved for patients who fail initial therapy. A number of drugs, including ATG, pentostatin, switching to tacrolimus from cyclosporine, and newer monoclonal antibodies (mAbs) have shown limited activity in the salvage treatment of patients with steroid-refractory aGvHD. Extracorporeal exposure of peripheral blood mononuclear cells (PBMCs) to the photosensitizing agent 8-methoxypsoralen and ultraviolet A (UVA) radiation (photopheresis) is effective in the treatment of selected diseases mediated by T cells, including both aGvHD and cGvHD, although the mechanism of this effect remains to be elucidated.

Autologous GvHD

A form of aGvHD can also occur after auto-HSCT, probably as a manifestation of immune system dysregulation during reconstitution of the immune system after dose-intensive therapy. Initially studied in murine models of auto-HSCT, it was demonstrated that the abrupt withdrawal of cyclosporine could induce clinical features nondistinguishable from that observed after allo-HSCT. A mechanism that involves the depletion of central memory cells has been proposed, although depletion of Tregs with inhibition of peripheral tolerance may also be involved. Autologous GvHD is also reported in patients not receiving posttransplantation immunomanipulations (spontaneous GvHD). Based on the clinical benefits of GvT observed in allo-HSCT, several clinical trials with administration of cyclosporine with or without interferon (IFN) were performed in patients undergoing auto-HSCT without obvious GvT effect.[13] Both induced and spontaneous autologous aGvHD are usually self-limiting complications, and are usually easily managed with a course of corticosteroids in patients with more extensive involvement, in contrast to the more extensive and difficult-to-manage aGvHD that occurs after allo-HSCT. Furthermore, cGvHD does not occur after auto-HSCT.

A spontaneously occurring severe, and sometimes fatal, reaction involving the gastrointestinal (GI) system with severe diarrhea during the periengraftment period is reported in patients undergoing auto-HSCT for MM and other malignancies ("engraftment syndrome").[14] The presentation is clearly distinct from the spontaneous or induced GvHD previously observed in patients undergoing auto-HSCT. "Engraftment syndrome" may be a consequence of prior treatments with immunomodulatory drugs, such as lenalidomide or thalidomide, the proteasome inhibitor bortezomib, or high doses of potent glucocorticoids before collection and storage of autologous HSCs, resulting in a period of immune dysregulation occurring early after autologous HSCT.[10] Patients with "engraftment syndrome" may require intensive treatment with corticosteroids and a calcineurin inhibitor, with courses more similar to those experienced by patients undergoing allo-HSCT.

Clinical Aspects of cGvHD

cGvHD is the leading cause of late transplant-related mortality (TRM) among those undergoing allo-HSCT and resembles autoimmune disorders, such as scleroderma, Sjögren syndrome, and primary biliary cirrhosis. Diagnosis is, as with aGvHD, based on clinical observations and secondary confirmation with laboratory or pathology tests (Table 83.2). A falling performance status, progressive weight loss, or recurrent infections are usually signs of severe cGvHD. About 50% of long-term survivors will develop cGvHD at a median of 9 months after transplantation, and patients must be monitored closely for this complication for at least 3 years so that appropriate treatment can be initiated before extensive end-organ damage ensues. Permanent ocular or oral sicca syndrome and pulmonary dysfunction can result if cGvHD is not appropriately treated, leading to a marked deterioration in quality of life.

Factors predictive of the development of cGvHD include the degree of HLA and miHA disparity, as well as prior aGvHD, older patient age, the source of HSCs (greater risk after peripheral blood stem cell [PBSC] transplantation than after bone marrow transplantation), gender (female donor–male recipient), and donor lymphocyte infusion (DLI) after transplantation. Inflammatory events, such as sunburn or surgical procedures, can precipitate cGvHD. Patients who develop cGvHD have a higher risk of TRM but a lower risk of relapse as a result of the immunological GvT effect.[15] T-cell depletion of the graft or treatment with ATG may decrease the risk of cGvHD, although this has not been demonstrated in all studies. Most patients require at least two drugs for effective treatment of cGvHD, with the standard initial treatment being glucocorticoids and a calcineurin inhibitor. About half the patients do not achieve a complete remission with first-line therapy, although the manifold signs and symptoms of cGvHD complicate the definition of response to treatment. There are no clear recommendations regarding second-line treatments and various pharmacological and immunological techniques have been used. Photopheresis has an overall response rate of 50–60%, with many patients achieving complete remission. At least transient responses can be achieved with rituximab treatment, an anti-CD20 chimeric antibody, which illustrates the humoral immunity contribution to cGvHD. The demonstration of activation of the Janus kinase (JAK) pathways in activated T lymphocytes has led to studies demonstrating a potential benefit of Jak2 inhibitors in the management of steroid-refractory cGvHD.

GvT Responses

Although recognized in mouse models of transplantation in the 1950s, the first clinical report of a relationship between GvHD and GvT was published in 1979.[16] This relationship between the incidence (but not the severity) of aGvHD or cGvHD and the relapse rate of chronic myeloid leukemia (CML) and, to a lesser extent, acute myeloid leukemia (AML), acute lymphocytic leukemia (ALL), and MM has been observed in patients who received allo-HSCT. Relapses after HSCT are thought to occur

TABLE 83.2 **Staging of Chronic Graft-Versus-Host Disease (GvHD)**

Target Organ	Score 0	Score 1	Score 2	Score 3
Performance score	KPS 100%	KPS 80–90%	KPS 60–70%	KPS <60%
Skin	No symptoms	<18% BSA	19–50% or sclerotic, still able to pinch	>50% or "Hidebound"
Mouth	No symptoms	Mild symptoms, no limitations	Moderate symptoms, decreased oral intake	Severe symptoms with major decrease in intake
Eyes	No symptoms	Mild dry eyes	Moderate dry eyes, drops >3×/day	Severe dry eyes affecting daily activities
Gastrointestinal tract	No symptoms	Symptoms without weight loss	Symptoms with moderate weight loss (5–15%)	Symptoms with weight loss >15%
Liver	Normal LFTs	LFTs elevated <2× upper limits of normal	LFTs elevated 2–5× upper limits of normal	LFTs elevated >5× upper limits of normal
Lungs	No symptoms	Mild symptoms FEV 60–79%	Moderate symptoms FEV 40–59%	Severe symptoms FEV <40%
Joints and fascia	No symptoms	Mild tightness not affecting daily activities	Tightness affecting daily activities	Contractures with significant loss of range of motion
Female genital tract	No symptoms	Symptomatic with middle signs on examination	Symptomatic with dyspareunia	Symptomatic with strictures

At least one diagnostic and one distinctive sign is necessary to make a diagnosis of cGvHD.
BSA, Body Surface Area; FEV, Forced Expiratory Volume; KPS, Karnofsky Performance Status; LFT, Liver Function Test.

CLINICAL PEARLS

Factors Predicting Chronic Graft-Versus-Host Disease (GvHD)

- Degree of human leukocyte antigen (HLA) incompatibility
  - Major histocompatibility complex (MHC)
  - Minor histocompatibility antigens (miHAs) disparity
- Presence of prior acute GvHD
- Source of stem cells (higher risk in peripheral blood versus bone marrow)
- Donor gender (female donor → male recipient)
- Use of donor lymphocyte infusion (DLI) following hematopoietic stem cell transplantation (HSCT)
- Inflammatory events; surgeries, phototoxicity, alcohol consumption

because of survival of malignant cells harbored in bone marrow after administration of the pretransplantation conditioning regimen and their outgrowth several months later. Relapse remains the major cause of treatment failure after allo-HSCT despite the intended GvT effect of this treatment modality. The ability to mediate an effective GvT response likely depends on several factors, including the presentation of appropriate antigens by MHC class I and/or class II molecules on the tumor cells that can be recognized by effector CD4 or CD8 T cells; lack of strong Treg activity that may be induced by cytokines from the tumor cells; tumor cell susceptibility to lysis by effector T cells (*e.g.*, the level of B-cell lymphoma 2 (BCL-2) expression and the ability to resist apoptosis induction); ability of T cells to home to sites of tumor growth; and the direct effect of immunosuppressive cytokines, such as transforming growth factor-β (TGF-β), produced by the tumor cells.[17] Many types of tumor cells downregulate expression of MHC on their surface, and perhaps CML and AML are most susceptible to GvT responses because the myeloid lineage is adapted for antigen presentation and high MHC expression. A number of novel immunotherapeutic approaches are being developed to overcome these obstacles and enhance GvT responses, keeping in mind that GvHD has to also be avoided or minimized to improve outcomes (Fig. 83.2).

FIG 83.2 Graft-Versus-Host Disease (GvHD) and Graft-Versus-Tumor (GvT) Responses. Donor T cell responses to recipient antigens can cause GvHD but can also target residual leukemia cells. T cells causing GvHD may recognize ubiquitous or tissue-restricted antigens (either major histocompatibility complex [MHC] or minor histocompatibility antigens [miHAs]). Many of these recipient antigens may also be expressed by the leukemia cells and allows for a GvT response. Additional leukemia-specific (*e.g.,* bcr-abl, proteinase 3, or c-akt) or tissue-restricted antigens (some miHAs, as those expressed only by certain lineages of hematological cells) may be dominantly expressed by the tumor cells and can be targeted by donor T cells without causing GvHD.

Immunotherapy remains the major strategy to combat relapse occurring after allo-HSCT. This can be achieved by reducing immunosuppression, offering a second allo-HSCT, or infusing additional lymphocytes from the HSC donor (DLI). As one can expect, all these modalities pose the challenge of associated morbidities, particularly GvHD.[6] More defined immunotherapeutic approaches using chimeric antigen receptors (CARs) expressed on T cells (CAR T cells; Chapter 77) also show some promise to target residual tumor cells that remain after allo-HSCT, with a possible low risk of GvHD. However, recent studies in murine models have raised a cautionary note concerning the capacity of CAR T cells to inflame GvHD.[18]

KEY CONCEPTS

Major Issues Related to Success of Allogeneic Hematopoietic Stem Cell Transplantation

- Graft-versus-host disease (GvHD)
- Graft-versus-tumor (GvT) responses
- Kinetics and completeness of immune reconstitution
- Opportunistic infections from delayed immune reconstitution
- Patient comorbid conditions increasing risk of toxicities
- Chemotherapy sensitivity of disease being treated

Immunomodulation is frequently the first treatment option for patients in relapse after allo-HSCT, with rapid withdrawal of immunosuppressive medications and infusion of donor T cells.[6] This treatment approach requires that donor T-cell chimerism be sustained to avoid rejection of effector cells through an HvG mechanism. Patients with low-grade lymphoid malignancies, such as CLL, indolent non-Hodgkin lymphoma (NHL), mantle cell NHL, and CML have the highest likelihood of response. A survey of 25 transplantation programs identified 140 patients who had received DLI and reported a complete response rate of 60% in patients with CML. Response rates were higher in patients with cytogenetic and chronic-phase relapse (75.7%) than in patients with accelerated-phase (33.3%) or blastic-phase (16.7%) relapse, and almost 90% of these patients remained in remission at 2 years after treatment.[19] The activity of DLI in AML and ALL is not as robust in comparison to that of in CML. However, it remains the main treatment strategy to treat relapse following allo-HSCT. DLI can be used in combination with chemotherapy to maintain control of disease control during the time required for the development of the GvT effect.

The number of lymphocytes infused is important in achieving the DLI effect, although it may be possible to induce GvT using doses of lymphocytes that are less likely to result in GvHD. A large retrospective analysis demonstrated that using an initially lower cell dose reduced GvHD and improved survival.[20] One method to reduce GvHD is to genetically insert suicide genes into the T cells being given for DLI, allowing specific ablation of these cells if this complication occurs.[21] Another method to lower GvHD rates complicating DLI is to deplete the DLI product of GvHD-inducing cells. Studies in mice have shown that naïve subset of CD8 T cells lead to more GvHD, whereas the effector memory subsets (T_{EM}) of CD8 and CD4 T cells moderate the graft-versus-leukemia (GvL) effect without causing GvHD.[22,23] The delay in response between DLI and the development of a GvT effect suggests that only a minority of the cells infused recognize the tumor cell antigens and must undergo *in vivo* expansion before the therapeutic effect is achieved. It may be possible to develop leukemia-specific cytotoxic T cells in the laboratory, decreasing the delay in effect and possibly increasing the GvT potential. Donor immunity can be transferred, at least transiently, to the host, as demonstrated by delayed-type transfusion reactions to host red blood cells (RBCs), mediated by donor lymphocytes transfused along with the HSC product.[24] Adoptive transfer of donor immunity against specific targets can be achieved, but its persistence requires immunization of both the donor and the recipient. A clinical utility for such manipulation of the immune system has not yet been demonstrated, but it is clearly of interest as a technique to prevent posttransplantation infections and/or disease relapse.

A rapid and major leap in the field of adoptive transfer of immunity is the development of CAR T–cell therapies for patients with aggressive lymphomas, ALL, MM, and CLL, resulting in long-lasting remissions following heavy pretreatment.[25] Developed in the late 1980s and requiring decades of fine-tuning and extensive clinical trials, CAR T cells have the ability to recognize and target tumor cells via their reprogrammed T-cell receptor (TCR) toward the malignant cell and costimulatory molecules engineered into the patient's own T cells. This form of treatment engaging a combination of gene therapy, cell therapy, and immunotherapy has led to unprecedented results in patients without robust treatment options for their aggressive malignancies or following relapse after allo-HSCT. The primary limitation of CAR T–cell therapy is the need to identify tumor-specific antigens to avoid the serious toxicity of "on target" but "off tumor" response.

Another potential approach to augment GvT responses following HSCT to prevent or treat relapse is the use of checkpoint inhibitors, currently accomplished by mAb blockade of negative regulatory signals from either cytotoxic T lymphocyte antigen-4 (CTLA4) or programmed death (PD)-1 proteins on the surface of activated T cells upon interaction with their respective ligands, B7-2 (CD86) and PD-L1 (B7-H1), on APCs and tumor cells (Chapter 77). Checkpoint inhibitors show strong clinical efficacy in the treatment of relapsed hematological malignancies, such as CLL and Hodgkin lymphoma.[26,27] In a phase I dose-escalation study using the anti-CTLA4 mAb ipilimumab for relapse after allo-HSCT, Bashey et al. concluded that ipilimumab did not induce or exacerbate clinical GvHD but could cause organ-specific immune adverse events and regression of malignancy following allo-HSCT.[28]

Adjuvant Therapy With HSCT

The relatively higher incidence of relapse after high-dose therapy leads to the hypothesis that chemoablation therapy with auto-HSCT, curative for some patients, could be viewed as a platform for other approaches effective in eliminating the minimal residual disease (MRD) in patients destined to experience relapse. Additional or yet higher-dose chemotherapy or radiotherapy, unless directly targeted to the tumor, increases the risk of nonhematopoietic toxicity and TRM from causes other than relapse. The correlation of more rapid lymphocyte recovery with a decreased risk of relapse, although likely a reflection of host factors and not direct evidence of a GvT effect after auto-HSCT, supports attempts to use HSCT as a tumor-debulking platform for posttransplantation immunotherapies. Immunotherapies are of interest in this regard and include administration of post-transplantation cytokines; the addition of tumor-specific antibodies, used before and/or after HSCT as an "*in vivo* purge"; and the development of tumor-specific vaccines, such as with tumor antigen–pulsed dendritic cells (DCs). The immunoglobulin (Ig) idiotype found in most patients with MM and indolent NHL, which is unique to the malignant clone, may serve as a unique tumor-associated antigen for DC pulsing. The treatment appeared to be well tolerated,[29] and after vaccination, idiotype-specific responses have been observed, characterized by T cell–proliferative responses with cytokine release and the production of antiidiotype antibodies, although, again, a clinical benefit remains elusive.

CLINICAL HSCT

Sources of HSCs

Bone marrow, peripheral blood stem cells (PBSCs), or UCB are all appropriate sources of HSCs for transplantation, with the primary differences being the quantities of HSCs in each product and the quantities and functions of other blood cells comprising most of the cellular content of the HSC product that may influence the immunological outcomes of transplantation. PBSCs have virtually replaced bone marrow as the HSC source for auto-HSCT and are widely used for allo-HSCT. Transplantation of PBSCs achieves more rapid hematological recovery in both the auto- and allo-HSCT settings, resulting in lower complication rates and lower costs of treatment. PBSCs appear to improve overall survival and disease-free survival of patients with advanced hematological malignancies who undergo allo-HSCT, although at the cost of an increased risk of extensive cGvHD.[30] Use of PBSCs results in a decreased CD4 T-helper cell-1 (Th1)/Th2 ratio, which may adversely affect the ability to counteract infections and may favor cGvHD development. It is also interesting to note that PBSC products tend to contain about 10 times more T cells than bone marrow products, yet those T cells are less functional, possibly because of inhibition by granulocytes activated by the granulocyte–colony-stimulating factor (G-CSF) used for HSC mobilization.[31]

UCB is a rich source of HSCs, with the major limitation for clinical use being the small quantity of cells collected, resulting in slower recovery of hematological function and increased risk of failure of sustained engraftment. A very significant advantage is the lower risk of GvHD because of the relative immaturity of the donor immune system, allowing for the use of HLA-mismatched units without a prohibitory increase in the risk of GvHD. In general, as with other sources of HSCs, outcomes of UCB transplantation reflect patient characteristics, with lower survival probabilities for patients with advanced diseases or poorer performance status at time of transplantation. A number of investigators proposed combining units of UCB to increase the cell dose infused into the patient, possibly increasing the speed of hematological recovery, but also (in theory at least, but not shown yet in clinical studies) potentiating the GvT effect and reducing the risk of relapse. *Ex vivo* expansion of one or more UCB units is also being studied as a mechanism to achieve more rapid hematological recovery.

Cell dose is an important predictor of outcome for both auto-HSCT and allo-HSCT, and HSCs comprise a very small portion (generally <1%) of the marrow, PBSC, or UCB product. It is now recognized that successful establishment of donor cell chimerism after allo-HSCT is a complex interplay of pre- and posttransplantation suppression of the host immune system, dose of HSCs and accessory cells (including donor lymphocytes) contained in the graft, and donor HLA compatibility (Fig. 83.3). HLA-mismatching, T-cell depletion, and less intensive pretransplantation conditioning regimens all raise the risk of graft failure. Importantly, the duration of aplasia predicts the incidence of TRM after auto-HSCT or allo-HSCT.[32] Auto-HSCT has a negligible risk of engraftment failure if the viability of HSCs is maintained during processing and storage. The speed of hematological recovery is related to the quantity of HSCs reinfused in an exponential relationship.[33] Increasingly higher CD34$^+$ cell (a surrogate marker of immature HSCs) doses result in greater likelihood of rapid recovery of PBSC counts. At lower doses, there is considerable heterogeneity in engraftment speed, especially for platelet recovery, with some patients experiencing quick engraftment despite low doses of PBSCs. Products containing ≥2-3 × 10^6 CD34$^+$ cells/kg recipient weight have more consistent rapid granulocyte and platelet engraftment.

Similarly, cell dose is a predictor of outcome for patients undergoing allo-HSCT. The actuarial 5-year TRM, overall survival, and disease-free survival significantly favored patients receiving marrow or PBSC grafts with higher cell doses,[34] but exceeding a CD34$^+$ cell dose of about 10 × 10^6/kg results in lower survival, likely as a result of higher risk of chronic GvHD.[35]

HSC products are not uniform in their characteristics, and the relative contributions of CD34$^+$ cell dose and the doses of

Influence of graft, donor, and host factors on allogeneic HSC engraftment

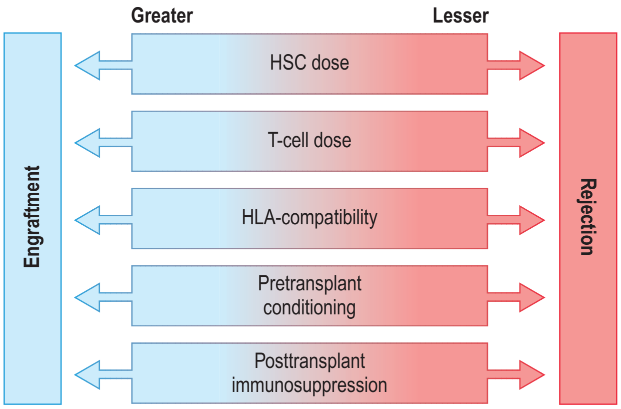

FIG 83.3 **Effect of Donor and Graft Characteristics on Allogeneic Hematopoietic Stem Cell Transplantation (Allo-HSCT).** Hematological engraftment requires that the host-versus-graft (HvG) reaction be overwhelmed, either by administration of a more intensive conditioning regimen before transplantation, use of more immunosuppressive medications after transplantation, closer matching of donor with host, and infusion of donor lymphocytes that can affect development of GvHD.

KEY CONCEPTS

Selection of Hematopoietic Stem Cell (HSC) Products for Transplantation

Bone Marrow

- Adequate quantities of cells can be obtained from most patients and donors
- Cytokine administration before harvesting may increase the quantities of HSCs collected and the number and function of accessory cells affecting transplant outcomes
- Lower risk of chronic graft-versus-host disease (GvHD) than peripheral blood stem cells (PBSCs)

PBSCs

- Faster hematological recovery than with bone marrow or umbilical cord blood (UCB)
- Better survival after related-donor hematopoietic stem cell transplantation (HSCT) for patients with advanced malignancy
- Lower tumor cell contamination than with bone marrow collected from autologous patients
- Cytokine administration before harvesting may increase the quantities of hematopoietic stem cells (HSCs) collected and the number and function of accessory cells affecting transplantation outcomes

UCB

- Relative immaturity of donor immune system permits multiple-antigen mismatched transplantation
- Transplantation outcomes similar to mismatched unrelated bone marrow transplantation
- Slower hematological recovery than with either PBSC or bone marrow
- Availability of stored units facilitates transplantation for patients with immediate need of treatment

accessory cells, including CD4, CD8, and NK-cell populations, on the outcome of transplantation remain unconfirmed. Whether or not this is clinically significant, the ratio and quantity of cell populations collected will be affected by changes in the cytokines and chemokines, used singly or in combination, to mobilize HSCs into peripheral blood for collection or to alter bone marrow products collected from patients and donors.

Purging of Cell Populations

For auto-HSCT, postcollection attempts to purge tumor cells potentially contaminating the graft have not demonstrated a survival advantage for the transplant recipient. T-cell depletion of donor HSCs by various methods is an effective means of reducing the incidence of aGvHD or cGvHD; but it increases the risk of graft failure, opportunistic infections, and relapse, effectively nullifying any advantage. Higher doses of HSCs, which can be achieved by the use of large quantities of PBSCs or by combining marrow and PBSC components, will offset this risk of graft failure. Partial T-cell depletion, as opposed to maximal T-cell depletion, may also reduce the risk of graft failure. Some centers are exploring posttransplantation T-cell add-back after the acute inflammatory effects of the conditioning regimen have resolved in an effort to maintain the GvT effect while still reducing GvHD morbidity and mortality.

Expansion of HSC Products

Ex vivo expansion of UCB HSCs is one potential mechanism to offset the low cell dose and delayed hematological recovery after transplantation. However, no expansion technique has yet achieved this goal, and such endeavors are complicated by the difficulty in identifying the pluripotent HSCs in comparison with lineage-committed progenitor cells. Furthermore, it is likely that expansion techniques will result in T-cell depletion, resulting in the other complications described above.

Hematological Recovery

HSC engraftment encompasses two concepts: *(i)* recovery of hematopoietic and immunological function and *(ii)* the rate at which this recovery occurs. Delay in or failure of sustained engraftment after myeloablative-conditioning regimen administration greatly increases treatment morbidity and cost. Engraftment failure can occur as a result of inadequate HSC quantity from poor collection or loss in postcollection processing, inadequate host support of the infused cells, posttransplantation events or medications, or HvG rejection (see Fig. 83.3). Engraftment failure is a very rare complication of auto-HSCT and is most likely a consequence of poor preservation of HSCs after collection. In allo-HSCT, the risk of engraftment failure is proportional to the donor HLA–miHA disparity, occurring more commonly in unrelated donor transplants than in sibling donor transplants, and with HLA-mismatched transplants. Engraftment failure is also increased by T-cell depletion of marrow inoculum because of the loss of the GvH effect against residual host immune cells.

Chimerism assessment is important in evaluating graft function after allo-HSCT. A fall in PBSC counts could indicate HvG rejection of the graft or early relapse after transplantation or could result from GvHD or viral infection. Documentation of stable persistence of donor T cells in the recipient's blood will help discriminate between these possibilities. It is also important that sustained lymphoid chimerism be demonstrated if DLI is to be used in the treatment of disease relapse after transplantation. The level of donor–host chimerism after allo-HSCT is best demonstrated through evaluation of single nucleotide tandem repeats (short tandem repeats [STRs]) by using molecular analysis. Obviously, such studies are of no value in assessing engraftment after auto-(syngeneic)HSCT.

Much of the emphasis in transplantation has been on myeloid engraftment because initial patient survival depends on recovery of phagocytes and, to a lesser extent, platelets. Immune reconstitution, and in particular donor T-cell reconstitution, in patients receiving HSCT is often hampered by older recipient age, diminished functional status of the thymus, cytokine milieu at the time of transplantation, and posttransplantation immunosuppressive treatments. The thymus involutes rapidly after childhood, and in the older adult, it is only able to contribute a very small portion to the mature T-cell compartment. The thymic tissue may be damaged as a result of a myeloablative conditioning regimen, or it can also be a target of alloreactive donor T cells mediating GvHD. As a result, restoration of the T-cell compartment in patients is often slow, particularly for CD4 T cells, and may be at suboptimal levels for many months to over a year. This situation, of course, endangers the ability of the patient to stave off opportunistic infections, such as from the herpes family of viruses and fungal pathogens. If donor T cells are provided in the HSC inoculum, some reconstitution of the T-cell repertoire, mostly CD8 T cells, is provided by the mechanism of nonthymic homeostatic expansion, although the level of diversity may be limited. Experimentally, administration of cytokines, such as interleukin-7 (IL-7), after HSCT, can enhance thymic function and help donor T-cell reconstitution. B-cell reconstitution, in contrast, is not that problematic in terms of the regeneration of the immune repertoire, although the ability to actually respond effectively to an infection with antibody production may still depend on the availability of antigen-specific CD4 T cells. Administration of Ig to patients with low IgG levels can prevent some of the infectious complications. Patients receiving HSCT who are conditioned with myeloablative regimens usually attain high levels of donor chimerism in their lymphoid compartment within a few months of transplantation. This often correlates with the ability of alloreactive donor T cells, capable of mediating GvHD, to target residual recipient HSC elements so that the primary source of *de novo* lymphoid reconstitution will be from the donor origin. By the same token, high donor chimerism is also associated with a lower incidence of relapse of malignancy.

CONDITIONING REGIMENS

Dose-Intensive and Reduced Intensity Chemotherapy

The pretransplantation regimen is intended to accomplish two goals: ablate the tumor and achieve adequate immunosuppression to allow donor engraftment. For auto-HSCT, only the dose-sensitivity of the tumor being treated need be considered. Lower dose, nonmyeloablative regimens are not used in auto-HSCT because with such regimens, infusion of HSCs to reconstitute marrow function would not be needed. Total body irradiation (TBI) was initially used for conditioning of transplant recipients. This modality achieves tumor cytotoxicity; treatment of sanctuary sites of disease, such as the central nervous system (CNS) and testes; and profound immunosuppression. TBI is usually combined in sequence with chemotherapy agents, such as cyclophosphamide or etoposide. Busulfan-based regimens were developed as alternatives to TBI for patients who had received prior dose-limiting radiotherapy and to avoid the effects of TBI on growth and development in children. A review of several studies that compared the use of busulfan and TBI found no statistically significant difference in survival or disease-free survival for patients with CML or AML.[36] Specific regimens are commonly used in the treatment of certain malignancies, such as dose-intensive melphalan in the treatment of MM and carmustine (BCNU)–containing regimens used in the treatment of lymphoma.

CLINICAL PEARLS

Conditioning Regimens for Hematopoietic Stem Cell Transplantation (HSCT) Transplantation

Autologous HSCT

- Allows dose-intensive therapy
- Allows use of marrow-toxic agents
- Regimens designed for optimal tumor cytotoxicity

Allogeneic HSCT

- Must achieve adequate patient immunosuppression (reduce host-versus-graft [HvG] reaction) to achieve engraftment
- Allows but does not require dose-intensive therapy
- Allows but does not require marrow-toxic agents
- Need not be tumor specific

The myeloablative conditioning regimens currently used have been tested in dose-escalation studies to achieve the maximal tolerated doses in otherwise healthy patients. Nonmarrow toxicities, such as pneumonitis, mucositis, and hepatic venoocclusive disease, limit further dose escalation of standard TBI- or chemotherapy-based regimens. New approaches include the addition of targeted therapies to the conditioning regimen, such as tumor-directed mAbs or radioimmunoconjugates that will not increase the toxicity to other organs. Tandem transplantation with the combination of a dose-intensive regimen with auto-HSCT followed, after recovery from the immediate regimen-related toxicities, by allo-HSCT using a reduced-intensity regimen is a novel approach to combine the benefits of each transplantation modality.

Hematological malignancies are predominantly diseases of older adults. The potent GvT effect that is observed after allo-HSCT allows allograft recipients to be treated with lower-dose nonmyeloablative regimens with the immunosuppressive properties of the regimen to reduce HvG reactions and facilitate engraftment becoming more important than direct cancer cytotoxicity. The primary requirement in developing a reduced-intensity regimen is the need to achieve adequate immunosuppression to permit the development of hematopoietic chimerism, which became feasible with the development of the purine analogue family of drugs. A variety of regimens are available, including combinations of fludarabine with melphalan and fludarabine with busulfan. Among the least toxic are regimens that involve a single fraction of TBI, based on the work by Storb et al.,[37] who proposed that the HvG reaction leading to HSC rejection and the GvH reaction could both be modified by an appropriate immunosuppressive regimen administered after transplantation, allowing a reduction in the intensity of the pretransplantation conditioning regimen.[37,38]

HSCT FOR INDIVIDUAL DISEASES

The treatment of diseases by auto- or allo-HSCT continues to evolve as the understanding of the biology of these diseases becomes more clearly understood. Improvements in nontransplantation treatments available to patients, such as the development of targeted tyrosine kinase inhibitors, which are very effective in the initial treatment of CML, will reduce the numbers of patients requiring HSCT in the management of their disease. Organizations, such as American Society of Blood and Marrow Transplantation, have published guidelines for treatment and reviews of the efficacy of treatment, identifying areas requiring additional research.[39,40]

Acute Myelogenous Leukemia

The primary clinical questions in HSCT in the treatment of AML concern patient selection and timing of treatment. Most patients with AML will achieve remission with initial chemotherapy, but even with appropriate postremission consolidation, the majority of patients (≈65%) will relapse within 1–2 years. Older age, the presence of defined cytogenetic abnormalities, inability to achieve a complete remission (CR) with the initial course of therapy, and history of a preceding marrow disorder or receipt of prior chemotherapy ("secondary AML") are predictors for failure of nontransplantation therapy. Patients with these adverse risk factors may be offered HSCT in first remission in place of nontransplantation consolidation chemotherapy. Numerous studies of patients entering their first remission compared standard consolidation therapy with dose intensification with auto- or allo-HSCT. In general, auto-HSCT was not shown to be more effective than nontransplantation consolidation chemotherapy, whereas allo-HSCT had the lowest risk of relapse. Despite the higher transplantation-related complications, in at least two major studies, patients assigned to allo-HSCT achieved a significantly better disease-free survival (DFS) compared with patients assigned to either chemotherapy or auto-HSCT. Allo-HSCT in first remission is particularly beneficial for patients with adverse risk features, achieving about a 50–70% DFS, and is the treatment of choice for patients with adverse risk cytogenetics or leukemia that arises from prior chemotherapy or other marrow diseases.

Myelodysplastic Syndromes

Myelodysplastic syndrome (MDS) comprises a heterogeneous group of clonal hematological disorders characterized by expansion of abnormal HSCs engendering variable degrees of cytopenia and frequent evolution to AML. Currently, allo-HSCT is the only modality of treatment that can achieve long-term control of disease; auto-HSCT is not feasible because of the inability to collect normal HSCs from these patients. The best results are seen in patients with earlier-stage disease, although for patients with earlier stage MDS, a "watchful waiting" approach, with transplantation performed at the time of disease progression, may be appropriate.

Chronic Myelogenous Leukemia

Allo-HSCT is an appropriate treatment for CML with long-term survival rates >80% for younger patients undergoing related donor transplantation within the first year after diagnosis. However, inhibitors of the tyrosine kinase (TK) encoded by the Philadelphia chromosome have relegated transplantation to the treatment of patients with advanced disease or the rare patient with CML not responsive to that targeted therapy. The probability of long-term survival is lower for patients who undergo allo-HSCT more than 1 year after diagnosis and for patients with more advanced diseases. The effect of prior therapy with a TK inhibitor on the outcome of transplantation is not known. CML is highly responsive to the immunological GvT effect, and many patients in relapse after transplantation can be salvaged by the administration of

DLI. CML is a stem cell disease, and the collection of normal HSCs is unlikely for most patients, precluding auto-HSCT. Of speculative interest is the collection of autologous cells after cytogenetic remission is achieved with the use of a TK inhibitor, for subsequent use at the time of disease relapse.

Myeloproliferative Diseases

MPDs are clonal stem cell diseases and include CML (discussed above), polycythemia vera, primary myelofibrosis, essential thrombocytosis, chronic myelomonocytic leukemia, and MPD not otherwise characterized. These disorders display overlapping clinical features and may also show features more characteristic of MDS, but they exhibit different natural histories and different therapeutic requirements. Allo-HSCT is effective in ablating the abnormal clone in these disorders. The timing of treatment is important because of the frequently long natural history of these diseases. Anemia, older age, and cytogenetic abnormalities all predict poor survival in primary myelofibrosis, suggesting that patients with anemia and an abnormal karyotype should proceed to allo-HSCT.

Acute Lymphoblastic Leukemia

In contrast to treatment of the pediatric patient with ALL (Chapter 78), only very few adults with ALL are cured with nontransplantation induction and consolidation regimens. As with AML, adverse risk features include certain cytogenetic changes and the inability to achieve remission with initial induction chemotherapy. Allo-HSCT in first remission is clearly effective in the management of patients with defined adverse risk cytogenetics, such as translocation involving chromosome 4 and 11, or 9 and 22 (Philadelphia chromosome). Recent randomized studies also demonstrate a survival advantage for patients who have intermediate risk of disease and are undergoing allo-HSCT, especially since current salvage regimens for patients in relapse have a very low likelihood of achieving a second remission. There is little evidence to support the effectiveness of auto-HSCT despite its theoretical potential.

Chronic Lymphocytic Leukemia

Many patients and physicians are reluctant to support aggressive treatment of CLL with allo-HSCT because of the frequently indolent nature and long natural history of this disease, as well as the advanced age of most patients at time of diagnosis. Yet disease progression is inevitable, and the aggressiveness of this disease can be predicted by various features, including chromosome 17p and 11q deletions and detection of ZAP-70 mutation and CD38 expression. Therefore HSCT should be considered a treatment choice, especially for younger patients or those with adverse risk features.

The exquisite sensitivity of the CLL cells to the GvT effect allows for the use of reduced-intensity regimens with lower risks of regimen-related mortality in these, generally, older patients. Durable control of disease can be achieved for about 50% of patients. The extensive infiltration of bone marrow by malignant lymphocytes and the lack of the GvT effect preclude auto-HSCT. In the few clinical studies that have been reported, high CR responses have been obtained with auto-HSCT, but relapses were the frequent cause of treatment failure.

Multiple Myeloma

MM is a malignancy of plasma cells (Chapter 80), with a median patient age of 65 years at time of diagnosis. In MM, dose-intensive melphalan with auto-HSCT can achieve about a 40% complete response rate. Tandem auto-HSCT with two cycles of dose-intensive therapy at 2- to 6-month intervals can improve progressive free survival and in some studies, overall survival. This approach to treatment is still debated. Ultimately, most patients experience relapse and succumb to the disease. Although auto-HSCT is not considered curative for this disease, the median duration of time without treatment is 2–3 years, and ≈15% of patients may not need treatment for progressive disease for 5 years or longer, which greatly improves their quality of life. Allo-HSCT with use of a reduced-intensity conditioning regimen decreases the risk of TRM to <10%, but patients with advanced disease are unlikely to respond to this treatment. The lower risk of complications with nonmyeloablative conditioning regimens has led to studies of tandem auto-HSCT, using an intensive chemotherapy regimen to achieve tumor debulking, followed 2–6 months later by allo-HSCT using a reduced-intensity regimen to achieve the GvT effect. This approach to the treatment of MM is being studied in large multicenter trials, with some studies showing a survival advantage for recipients of allo-HSCT.

Non-Hodgkin Lymphoma

The lymphomas (Chapter 79) represent a diverse group of malignant diseases of B and T lymphocytes, comprising some of the slowest- to the fastest-growing human malignancies, with a range of curability achieved by nontransplantation therapies. As a group, the lymphomas exhibit a strong dose–response relationship to chemotherapy or radiotherapy, and the benefit of dose-intensive treatment with auto-HSCT has been well established. Auto-HSCT avoids the morbidity of allo-HSCT and is the preferred approach for the majority of patients, with some prominent exceptions discussed below. Popular chemotherapy regimens include cyclophosphamide, BCNU, and etoposide (CBV) or BEAM (BCNU, etoposide, cytarabine, and melphalan). However, no single chemotherapeutic or radiation-based regimen has emerged as a superior treatment.

Low-Grade NHL

Low-grade NHL, in general, exhibits a variable and prolonged natural course, with many patients not requiring treatment until symptoms or organ toxicity appear. Therefore most of the experience with HSCT has been in patients after initial relapse rather than at the time of initial diagnosis. Few randomized studies comparing auto-HSCT with nontransplantation therapies for patients have been reported. A number of phase II and registry data have been published for auto-HSCT, and although response rates are high, a continuing pattern of relapse has been observed. In contrast, patients who undergo allo-HSCT experience a higher probability of TRM but a lower risk of relapse after transplantation. Indolent B-cell NHL, similar to other low-grade diseases, such as CLL, appears to be very sensitive to the GvT effect of allo-HSCT, and using reduced-intensity regimens will result in lower transplantation-related complications. The difference in relapse rates between auto-HSCT and allo-HSCT could result from the possible reintroduction of lymphoma cells in the HSC product but is more likely from the lack of a GvT effect of auto-HSCT.

Aggressive NHL

Auto-HSCT is the standard of care for patients with B-cell NHL in first “chemotherapy-sensitive” relapse. The success of this therapy reflects the extent and the responsiveness of the disease to chemotherapy at the time of transplantation, with relapse the major cause of treatment failure. The Parma randomized trial for high-dose therapy followed by auto-HSCT reported a significantly higher event-free survival for patients treated with auto-HSCT than for the group receiving standard-dose treatment (46% vs 12%). Furthermore, it is notable that no patients assigned to the conventional-dose salvage therapy could be rescued at the time of the second relapse with delayed transplantation. The efficacy of auto-HSCT is diminished for patients previously treated with rituximab, an anti–B-cell chimeric antibody, and who relapse within 12 months of initial therapy.[41] Other circumstances, in which HSCT may be indicated, include HSCT for patients who respond slowly to initial therapy, have high-risk disease, are resistant to initial therapy, or are in relapse with chemotherapy-insensitive disease.[40] Results for patients with truly chemotherapy-refractory disease are, however, poor, and such patients should be considered for allo-HSCT.

Mantle cell lymphoma is known for its unremitting clinical course when treated conventionally and has proven relatively resistant to dose-intensive treatment, especially when used for management of relapsed disease. Mantle cell NHL appears to be very sensitive to the GvT effect of allo-HSCT allowing treatment with reduced-intensity regimens.

Burkitt lymphoma, Burkitt-like lymphomas, and lymphoblastic lymphomas are high-grade NHLs associated with relatively poor long-term survival rates. The role of both auto-HSCT and allo-HSCT in these disorders remains unclear. There are no convincing risk models that identify clear indications for transplantation as part of the initial therapy. The lack of an obvious GvT effect in these disorders suggests that auto-HSCT can provide a reasonable treatment. Transplantation registry data suggest that disease status at the time of transplantation is the most important predictor of outcome in patients with high-grade disease.[42] T-cell lymphomas are less common than B-cell lymphomas. There is no well-defined management strategy for these disorders, and treatment is based on the disease stage and immunopathological grade. Disease control with T cell–type treatment regimens, compared with the more common B cell–type treatment regimens, is lower, although the comparison may not be appropriate, as T-cell diseases present at more advanced stages compared with B-cell diseases. The GvT effect may be more evident in T-cell NHL, particularly for virus-associated NHL, and allo-HSCT is the preferred treatment for some patients.

Hodgkin Lymphoma

Many patients with Hodgkin lymphoma will achieve durable remissions with nontransplantation chemotherapy and/or radiation therapy, and algorithms for staging and treatment of this disease are well defined. Dose-intensive therapy with auto-HSCT is available to those patients who do not achieve a remission or who relapse after initial therapy. The outcome for patients whose remission lasted <1 year is dismal with standard dose second-line treatments, and approximately 40–50% of patients with Hodgkin lymphoma who suffer a relapse within 1 year will achieve durable remissions after auto-HSCT. This approach can also overcome drug resistance and lead to an overall survival rate of 34–50% for patients with chemotherapy-refractory disease.

Allo-HSCT is not the first choice for the treatment of relapsed Hodgkin lymphoma because of the higher transplantation-related complications despite the evidence of an effective GvT effect. Allo-HSCT is offered to patients who suffer relapse after auto-HSCT or who are not candidates for auto-HSCT because of aggressive, chemotherapy-refractory disease.

Solid Tumors

Skin and colonic mucosa are primary targets of both acute and cGvHD, and this would suggest that allo-HSCT would be effective therapy in the treatment of cancers of these organs. Yet allo-HSCT is not effective in the control of these cancers, illustrating the discrimination between target antigens of normal tissues of GvH, such as the colonic crypt cells, compared with antigens expressed by tumors derived from these tissues targeted by GvT. With the exception of allo-HSCT in the treatment of renal cell cancer, in which a GvT effect was seen to be clinically evident in some but not all studies, transplantation in the treatment of solid tumors, such as neuroblastoma, Wilm tumor, and germ cell tumors, is limited to auto-HSCT with one or more cycles of dose-intensive chemotherapy.

FUTURE DIRECTIONS

Advances in HLA typing, chemotherapy conditioning regimens, supportive care, and our understanding of the biology of the HvG and GvH reactions have greatly reduced the toxicity of both auto-HSCT and allo-HSCT. Although the diseases treatable with HSCT are those characterized by dose sensitivity, currently available dose-intensive conditioning regimens have been pushed to maximal tolerable doses. Newer approaches to the treatment of these malignancies will likely include the addition of therapies that target the malignancy, such as radioimmunoconjugates that will add minimal toxicity to other organs. The availability of reduced-intensity regimens permits tandem transplantation, using dose-intensive therapy with auto-HSCT to achieve maximal tumor-cell debulking, followed, after recovery from transplantation-related toxicities, by Allo-HSCT, using a reduced-intensity regimen to achieve an immunological GvT effect. Advancements in the field of haploidentical HSCT have facilitated immediate availability of donors for patients with high-risk malignancies when selection of unrelated donors is limited by ethnicity and time constraints. Finally, the ability to use HSCT as a platform for protein- or cellular-based vaccination strategies is the subject of considerable interest.

ON THE HORIZON

Allogeneic Hematopoietic Stem Cell Transplantation (HSCT)

Development of donor selection algorithms
Strategies to maximize graft-versus-tumor (GvT) effect
Advent of haploidentical HSCT allows for easy donor availability
Refining haploidentical HSCT techniques for different diseases and use of KIR testing for donor selection
Combination conditioning regimens
Developing regimens with lower toxicities
Posttransplantation maintenance/treatment
Posttransplantation maintenance/treatment for high risk of relapse after HSCT
Immune effector cell therapies
Platform for other treatments; chimeric antigen receptor (CAR) T–cell therapy, checkpoint inhibitor blockade

Autologous HSCT

Tumor-specific conditioning regimens
Improve ratio of toxicity to tumor-cell cytotoxicity
Posttransplantation vaccination strategies
Checkpoint inhibitor blockade in clinical trials for high-risk malignancies

MULTIPLE-CHOICE QUESTIONS

1. What is the objective of using a conditioning regimen for hematopoietic stem cell transplantation (HSCT)?
   A. To reduce the bulk of malignant cells
   B. To decrease the risk of graft rejection
   C. To improve the engraftment of donor hematopoietic stem cells (HSCs)
   D. All the above

2. What is the main mechanism of graft-versus-leukemia (GvL) effect using donor lymphocyte infusion?
   A. Release of cytokine mediators generated by the graft-versus-host disease (GvHD) reaction initiated by donor lymphocyte infusion (DLI)
   B. Provide CD4 and CD8T cells that recognize target antigens on tumor cells
   C. Enhance inhibitory receptors (killer cell immunoglobulin-like receptors [(KIRs]) recognized by donor natural killer (NK) cells
   D. Increase the T-cell receptor (TCR) repertoire diversity

3. Which of the following increases the risk of relapse after an allogeneic stem cell transplantation?
   A. Human leukocyte antigen (HLA) mismatched donor
   B. $CD34^+$ cell dose less than 2×10^6/kg patient weight
   C. Presence of acute or chronic GvHD
   D. Disease burden prior to stem cell transplantation

4. Use of which strategy decreases the risk for acute and/or chronic GvHD?
   A. Unrelated donor
   B. Female donor for male recipient
   C. Total body irradiation as part of the conditioning regimen
   D. T-cell depletion of graft

Immunoglobulin Therapy: Replacement and Immunomodulation

Mark C. Ballow

Over 70 years ago, a cold ethanol fraction of plasma that contained an enriched fraction of gammaglobulin was used intramuscularly as passive immunotherapy for the treatment and protection of infectious pathogens and subsequently as antibody replacement therapy for patients with primary immune deficiency diseases (PIDDs). This Cohn ethanol plasma fraction of immunoglobulin G (IgG) remained the principal form of therapy until 1981 when an intravenous (IV) preparation (*i.e.,* intravenous immunoglobulin [IVIG]) became available. Subsequently, Imbach observed that thrombocytopenia resolved when patients with immune deficiency were treated with IVIG. This observation led to the use of IVIG in patients with autoimmune idiopathic thrombocytopenic purpura, and an expansion on the use of IVIG as immunomodulatory therapy in several FDA approved autoimmune disorders (Table 84.1). Most IVIG preparations are derived from plasma by the Cohn ethanol fractionation method or the Cohn-Oncley modification. IVIG products are modified to prevent the formation of IgG aggregates and to make IVIG suitable for the IV route. Excipients, such as sugars (maltose or D-sorbitol) or amino acids (glycine or L-proline), stabilize the IgG molecules from aggregation. Cold ethanol fractionation as the first step in plasma processing inactivates human immunodeficiency virus (HIV). Treatment with low pH, solvent and detergent, pasteurization or nanofiltration/depth filtration in combination, depending on the Ig product, is used as further 5–7 steps for viral inactivation and removal. Commercial lots of IVIG are derived from ≈15 000 donors (not to exceed 60 000 donors according to the U.S. Food and Drug Administration [FDA] and the Plasma Protein Therapeutics Association). Each lot must contain adequate levels of antibody to measles. These products may vary slightly among manufacturers and from lot to lot, but they are generally comparable with regard to clinical efficacy, but perhaps not tolerability. The newer Ig formulations are isoosmolar, low-sodium, and low-IgA liquid products. The characteristics of IVIG preparations available in the United States are reviewed in Table 84.2.

In this chapter, the application of IVIG as replacement therapy in patients with primary immune deficiency (PID) and the potential mechanisms of action of Ig therapy in the treatment of autoimmune and inflammatory diseases are reviewed. For more information on the use of Ig therapy in specific diseases, the reader is referred to an evidence-based review of the topic elsewhere.[1,2]

KEY CONCEPTS 1

Properties of Intravenous Immunoglobulin (IVIG) and Subcutaneous Immunoglobulin (SCIG)

- Plasma fractionation (first step) by cold ethanol / Cohn-Oncley modification (fraction II)
- >98% IgG; >90% monomeric IgG
- Traces of other immunoglobulins (*i.e.,* IgA and IgM) and serum proteins
- Addition of sugar, and amino acids, stabilizes IgG from aggregation
- Multiple viral inactivation/removal steps
  - Cold ethanol fraction
  - Chromatography
  - Solvent/detergent treatment
  - Caprylate fractionation
  - Nanofiltration
  - Depth filtration
  - Pasteurization
- Intact Fc receptor important for biological function
  - Opsonization and phagocytosis
  - Complement activation
  - Antibody dependent cytotoxicity
- Normal half-life comparable to serum IgG
- Normal proportion of IgG subclasses
- Broad spectrum of antibodies to bacterial and viral agents

REPLACEMENT THERAPY WITH IVIG

Several early trials in the 1980s have been conducted to examine the efficacy of IVIG with intramuscular (IM) gammaglobulin, and a comparison of low-dose with high-dose IVIG therapy. Quartier et al.[3] performed a retrospective study of the clinical features and outcomes of 31 patients with X-linked agammaglobulinemia receiving replacement IVIG therapy between 1982 and 1997. Although early treatment with IVIG and achieving a trough serum IgG level of >500 mg/dL was effective in preventing severe acute bacterial infections, these levels did not prevent pulmonary disease, sinusitis, or meningoencephalitis. The authors suggested that more intensive therapy to maintain a higher serum IgG trough level (*e.g.,* >800 mg/dL) may improve the pulmonary outcome.

Several studies have shown that pulmonary abnormalities are the most important factors associated with morbidity and mortality in patients with PIDs. The number of infections, days on antibiotic therapy, days missed from school or at work, and hospitalized days may not be sufficient indicators of adequate treatment. Therefore the improvement or maintenance of pulmonary function is an important measure of the success of therapy. Orange et al.[4] examined the impact of serum IgG trough levels on pneumonia incidence in patients with PIDDs receiving replacement IVIG therapy in a meta-analysis of published clinical

TABLE 84.1 FDA-Approved Indications for IVIG

- Primary humoral immunodeficiency disease—as replacement therapy
- Immune thrombocytopenic purpura—to prevent severe bleeding
- Children with HIV/AIDS and recurrent infections—to prevent serious bacterial infections
- B-cell chronic lymphocytic leukemia with recurrent infections and humoral immune deficiency—to prevent bacterial infection
- Kawasaki disease—to prevent coronary artery aneurysms
- Bone marrow transplantation—to decrease risk of infection, interstitial pneumonia, and graft-versus-host disease in the first 100 days after transplantation
- Chronic inflammatory demyelinating polyneuropathy
- Multifocal motor neuropathy

FDA, U.S. Food and Drug Administration; *IVIG,* intravenous immunoglobulin; *HIV,* human immunodeficiency virus; *AIDS,* acquired immunodeficiency syndrome.

KEY CONCEPTS 2

Treatment of Patients With Primary Immune Deficiency With Intravenous Immunoglobulin

- Starting dose—400–600 mg/kg every 4 weeks.
- Maintain trough level of >500 mg/dL or a serum immunoglobulin G (IgG) level 450 mg/dL over baseline.
  - Recent studies indicate the most patients may require a trough or steady-state level of 750–850 mg/dL.
  - The most important dose of intravenous immunoglobulin (IVIG) is the dose that keeps the patient free of infections (*i.e.*, biological trough level).
- Higher trough levels (>800 mg/dL) may be necessary to prevent chronic pulmonary changes and enteroviral meningoencephalitis.
- Depending on the IgG catabolism and/or control over infections, decrease infusion interval to every 3 weeks.
- Subcutaneous immunoglobulin (SCIG) offers an advantage in achieving higher steady-state plasma IgG levels.
- It may take ≥3 months to achieve a steady state after a change in dose.
- Monitor serum blood urea nitrogen (BUN) and creatinine and perform liver function tests every 6–12 months.
- Keep a log of dose, manufacturer, lot number, and reactions for each infusion.
- For patients with rate-related adverse side effects. Consider pretreatment with:
  - Acetaminophen
  - Diphenhydramine
  - Nonsteroidal antiinflammatory drugs (NSAIDs)
  - Corticosteroids
- Consider alternate administration of SCIG in patients with frequent systemic adverse reactions.

studies. The results of their analysis showed that trough IgG levels increased 121 mg/dL for every 100 mg/kg increase in dose, which resulted in a decrease in pneumonia incidence by 27%. There was a strong correlation between increasing trough IgG levels and a decrease in pneumonia. Bonagura et al.[5] discussed the value of "biological" trough levels for the serum IgG related to the patient's clinical course (*i.e.,* frequency of infections) instead of arbitrarily choosing a trough value of 500 mg/dL. A study of 90 patients with common variable immune deficiency (CVID) with follow-up of 22 years showed that the dose of IVIG needed to keep a patient free of infection varied among patients, emphasizing that the goal of replacement therapy should be improvement of clinical outcome, not a specific IgG trough level.[6]

The overall consensus among clinical immunologists is that an IVIG dose of 400–600 mg/kg/month is a good *starting point*. (see Key Concepts 2) Catabolism of infused Ig varies among individuals. The rate of elimination of IgG may be higher during a period of active infection. For persons with a higher catabolism of infused IgG or more frequent infections, infusions every 3 weeks with smaller doses may be more efficacious. In the final analysis, trough levels are only a general guide, and the clinical well-being of the patient is a more important parameter. Clearly, with higher trough levels, the incidence of pneumonia and comorbid conditions (*e.g.,* bronchiectasis and meningoencephalitis) is reduced.[3-6]

For replacement therapy in patients with PID all brands of IVIG are probably equivalent, although there are differences in viral inactivation processes (see Table 84.2). The choice of brands may be dependent on the hospital, payor, or home care formulary; the distributor availability and cost; and, most importantly, patient tolerability. The dose, manufacturer, and lot number should be recorded for each infusion to facilitate review procedures for adverse events or other consequences. It is crucial to record all side effects that occur during the infusion. It is also recommended that liver and renal functions be monitored periodically, approximately once or twice a year. Changes in weight or growth in children or changes in clinical response or adverse events may necessitate a more frequent laboratory evaluation. More frequent serum IgG levels may be necessary for patients on home therapy, especially for those receiving subcutaneous (SC) products to evaluate compliance.

In patients with active infection, especially patients with CVID, the initial (first) dose can be halved (*i.e.,* 200–300 mg/kg) and the dose repeated 2 weeks later to achieve a full dose. To minimize cost and inconvenience, self-administration and home treatment have been used successfully. For home therapy, patients need to be selected carefully. Infusions should be done only in the presence of a responsible adult who is ready to provide assistance. Home treatment has been reported to be as effective as hospital treatment in terms of the frequency of infections, days missed from school or work, antibiotics used, and Ig level achieved. Patients receiving home treatment should be seen regularly (*i.e.,* approximately every 6 months) to monitor clinical status, liver function, and serum IgG level.

The first description on the use of the SC route for Ig replacement therapy was published in 1980. It was reported to be safe, well tolerated, and effective in achieving adequate serum IgG levels. In a multicenter study of 165 patients with hypogammaglobulinemia receiving subcutaneous infusions (27 030 at home), a significant reduction in adverse systemic reactions with SC administration, compared with the IM or IV administration, was observed. Anaphylactoid reactions did not occur. Several studies have shown enhancements in quality-of-life measurements.[7,8] Local tissue reactions occur with subcutaneous immunoglobulin (SCIG) infusions, including swelling, soreness, redness, induration, local heat, itching, and bruising. There are advantages and disadvantages for each of the routes of administration of replacement Ig therapy. (Clinical Pearls)

SCIG is a suitable alternative to IVIG and may present certain opportunities for optimizing care for patients with PIDD at home.[9] SCIG is an excellent alternative to IVIG for those patients unable to tolerate the IV route of Ig replacement due to systemic side effects with IVIG administration. SCIG also leads to higher serum IgG steady-state levels[10] and may eliminate the wear-off effects of IVIG replacement therapy.[11,12]

TABLE 84.2 Characteristics of Immunoglobulin (Ig) Preparations

Brand (Manufacturer)	Manufacturing Process	pH	Stabilizer/ Sodium	Parenteral Form and Final Concentrations	IgA Content (µg/mL)	Antiviral Steps
Intravenous IgG						
Gammagard S/D (Shire)	Cohn-Oncley cold ethanol fractionation, followed by ultracentrafiltration and ion exchange chromatography	6.4–7.2	Albumin, glycine, glucose; sodium 8.5 mg/mL / 17 mg/mL	Lyophilized powder 5%, 10%	<2.2 µg/mL (5% solution)	PEG precipitation, solvent detergent treated, low pH, depth filtration
Gammagard Liquid (Shire)	Cohn-Oncley cold ethanol fractionation, followed by ultracentrafiltration and ion exchange chromatography	4.6–5.1	Glycine; trace sodium	10% liquid solution	37 µg/mL	S/D treatment, nanofiltration, low pH incubation
Gamunex -C (Instituto Grifols, SA)	Cohn-Oncley cold ethanol fractionation, diafiltration and depth filtration; caprylate/ anion-exchange chromatography	4.0–4.5	Glycine; trace sodium	10% liquid solution	46 µg/mL	Caprylate precipitation, depth filtration, low pH incubation
Privigen (CSL Behring AG)	Cold alcohol fractionation, octanoic fractionation, chromatography and depth filtration	4.6–5.0	L-Proline trace sodium	10% solution	≤25 µg/mL	Depth filtration, pH4 incubation, nanofiltration, TSE reduction steps
Gammaked (Grifols -Distributed by: Kedrion Biopharma)	Cohn-Oncley cold ethanol fractionation, diafiltration and depth filtration; caprylate/ anion-exchange chromatography	4.6–4.5	Glycine	10% liquid solution	46 µg/mL	Caprylate precipitation, depth filtration, low pH incubation
Flebogamma DF (Instituto Grifols, SA)	Cold alcohol fractionation, ion exchange chromatography, polyethylene glycol precipitation,	5.0–6.0	D-Sorbitol	5% and 10% liquid solution	<50 µg/mL for the 5%	PEG precipitation, pasteurization, S/D treatment, nanofiltration, pH4 treatment
Octagam (Octapharma)	Cohn-Oncley cold ethanol fractionation, chromatography	5.1–6.0	Maltose	5% and 10% solution	<100 µg/mL	Solvent/detergent, pH4 incubation, ultrafiltration
Gammaplex (Bio Products Laboratory)	Kistler & Nitschmann fractionation, chromatography, DEAE Sephadex chromatography, CM-Sepharose chromatography	4.8–5.1	D-sorbitol, glycine and polysorbate 80 Sodium 30–50 mmol/L	5% solution	<10 µg/mL	S/D treatment, nanofiltration, low pH incubation
Bivigam (Biotest Pharmaceuticals Corporation)	Cohn-Oncley cold ethanol fractionation, ion-exchange chromatography	4.0–4.6	Glycine 0.1–0.14 M sodium	10%	≥ 200 µg/mL	S/D, nanofiltration, fraction precipitation
Carimmune NF (CSL Behring AG)	Kistler & Nitschmann fractionation, Cold alcohol fractionation, Chromatography, nanofiltration	6.4–6.8	Sucrose <20 mg sodium/g protein	Lyophilized preparation—3%, 6%, 9%, or 12%	720 µg/mL	pH4, trace pepsin, depth filtration, nanofiltration, TSE reduction steps
Subcutaneous IgG						
Hizentra (CSL Behring AG)	Cold alcohol fractionation, octanoic acid fractionation, anion exchange chromatography	4.6–5.2	L-Proline Trace sodium	20%	≤50 µg/mL	Depth filtration, pH4 incubation, depth filtration, nanofiltration, TSE reduction steps
Gamunex-C (Instituto Grifols, SA)	Cold ethanol fractionation, diafiltration and depth filtration; caprylate/anion exchange chromatography	4.0–4.5	Glycine; trace sodium	10%	46 µg/mL	Caprylate precipitation, depth filtration, low pH incubation
Gammaked (Grifols -Distributed by: Kedrion Biopharma)	Cold ethanol fractionation, Depth filtration, caprylate/ anion-exchange chromatography	4.6–4.5	Glycine	10%	46 µg/mL	Caprylate precipitation, depth filtration, low pH incubation
Gammagard Liquid (Shire)	Cohn-Oncley cold ethanol fractionation, followed by ultracentrafiltration and ion exchange chromatography	4.6–5.1	Glycine; trace sodium	10% solution	37 µg/mL	S/D treatment, nanofiltration, low pH incubation
HyQvia (Shire)	Cohn-Oncley cold ethanol fractionation, followed by ultracentrafiltration and ion exchange chromatography	4.6–5.1	Glycine	10% plus human recombinant hyaluronidase	37 µg/mL	S/D treatment, nanofiltration, low pH incubation
CUVITRU (Shire)	Cohn-Oncley cold ethanol fractionation, followed by ultracentrafiltration and ion exchange chromatography	4.6–5.1	Glycine	20%	80 µg/mL	S/D treatment, ultra/ diafiltration, low pH incubation

Contents of table summarized from manufacturers' literature.

PEG, polyethylene glycol; *S/D*, solvent detergent; *TSE*, transmissible spongiform encephalopathy.

CLINICAL PEARLS 1

Comparison of Routes of Administration of Immunoglobulin Therapy in Patients With Primary Immune Deficiency

Intravenous (IV) Route

Advantages

- Achieve rapid plasma levels
- Can use this route in patients with bleeding disorders
- 3–4 week intervals

Disadvantages

- Need IV access
- Interrupt patient's schedule for 3–5-hour period
- Often needs to come to a hospital or infusion center
- System side effects may be more frequent in some patients

Subcutaneous (SC) Route

Advantages

- IV access not needed for those patients with poor venous access
- Eliminate trough levels
  - Achieve a stable serum level of immunoglobulin G (IgG)
  - May eliminate 3rd–4th week fatigue prior to next infusion (wear off)
- Less systemic adverse effects than IV route
- More flexibility for patient's (parent's) schedule
  - Distance from infusion center or hospital
  - Young adults going to college

Disadvantages

- Minor local reactions at the site of infusion
- Patient reliability
- Need for a pump

SCIG products are 10% or 20% formulations, the former being similar in composition to IVIG products. The calculated dose for SC administration is generally 100–150 mg/kg weekly. Depending on the weight or body mass of the patient and the concentration of the SCIG (*i.e.,* 10% or 20%), infusions may have to be given more frequently than every 7 days. Pharmacokinetics studies in clinical trials have suggested that upward adjustments in the dose of 37% of the IVIG dose may be needed to achieve comparable bioavailability, defined as the area under the serum concentration curve (AUC).[13] This adjustment in dosing between IVIG and SCIG has not been mandated by European regulatory agencies, and in the United States some clinical immunologists select dosing based on optimization of prevention of infections, as noted above for the IVIG dosing.[5,6] Each subcutaneous infusion requires a small portable syringe driver–type pump together with a 10–20-mL syringe and an infusion set with a specialized SC 25–27-gauge needle. The length of the needle may have to be adjusted for the thickness of the subcutaneous tissue of each patient. Before infusion, the line needs to be checked to ensure that there is no blood return. Infusions can be given weekly at multiple sites or more often (*e.g.,* daily), if needed, to maintain adequate serum IgG levels. The 20% SCIG product can be given every 2 weeks. Infusion sites are usually on the abdominal wall and lateral thigh. In adults, 20–35 mL can be infused into a single site, depending on the amount of subcutaneous tissue. A general guideline for infusion rate is 15–35 mL/hr per site depending on the weight and subcutaneous tissue of the patient. The SCIG schedule should be started 1 week after the last dose of IVIG, or in a new patient loaded with 4 or 6 doses of SCIG. Before home treatment, patients need to be instructed on the correct technique, made to apply it under close supervision, and educated about the recognition of possible side effects. SCIG infusion is safer, better tolerated, and preferred by some patients. Several studies in Europe and Canada have shown that health care costs of SCIG therapy are lower compared with IVIG.[14-16] It should be considered as an alternative, especially in those patients with systemic adverse reactions from IV administration. Recently, an alternative method for the administration of Ig has been approved and has been referred to as *facilitated SC infusion.*[17,18] In this approach, human recombinant hyaluronidase is used to enhance the volume of Ig (10% liquid Ig) that can be infused in the SC space, allowing for monthly doses of Ig to be administered in one or two sites. The hyaluronidase depolymerizes the hyaluronan temporarily allowing the Ig greater access to the lymphatics of the SC space, facilitating the absorption of Ig. This method of administration of 10% Ig has been shown in pharmacokinetic studies to result in bioavailability of 93% of the IVIG dose and thus does not require an upward adjustment factor in calculating the dose of Ig replacement. More details about SC infusions can be found in several reviews.[11,19,20]

ADVERSE EVENTS ASSOCIATED WITH IVIG THERAPY

Rate-Related Adverse Events

Typical rate-related adverse reactions with IVIG include tachycardia, dyspnea, chest tightness, back pain, arthralgia, myalgia, hypertension or hypotension, headache, pruritus, rash, and low-grade fever. Mild to moderate reactions occur in 5–15% of infusions; severe reactions occur in <1% of patients. Of course, in patients with autoimmune disorders, reaction rates are higher with higher doses. Patients with more profound immunodeficiency or patients with active infections also tend to have more severe reactions. Other factors that contribute to adverse reactions include change of IVIG products, concomitant infections, higher concentrations or lyophilized products, and rapid infusion rates (reviewed in the report by Stiehm[21]). The cause of the reactions is thought to be related to the anticomplementary activity of IgG aggregates in the IVIG in which immune complexes form between infused antibodies and antigens of infectious agents in the patient. The other possible mechanism is that the formation of oligomeric or polymeric IgG complexes interacts with Fc receptors and triggers the release of inflammatory mediators. These rate-related reactions occur less frequently with the newer IVIG products that are liquid and isoosmolar. Headaches are the most frequent symptom associated with IVIG infusions occurring in 5–20% of infusions and one-third of patients. Slowing the infusion rate or discontinuing therapy until symptoms subside may diminish the reaction. Pretreatment with nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen (15 mg/kg/dose), diphenhydramine (1 mg/kg/dose), and/or hydrocortisone (6 mg/kg/dose, maximum 100 mg) 1 hour before the infusion may prevent adverse reactions. Oral hydration prior to the infusion is often helpful. Switching products may also lead to adverse events in 15–18% of patients and should be discouraged.

Central Nervous System–Related Adverse Events

Aseptic meningitis has been reported as one of the complications of IVIG, especially with large doses and rapid infusions and in the treatment of patients with autoimmune disease.[21] Interestingly, this rarely occurs in subjects with immunodeficiencies. Symptoms,

CLINICAL PEARLS 2

Adverse Events Associated With Immunoglobulin Therapy

Rate-Related

- Infusion site erythema, swelling, pain, itching
- Headache
- Myalgia, back pain, arthralgia
- Malaise, fatigue
- Chills, Fever
- Pruritus
- Rash—urticaria
- Nausea, vomiting
- Tachycardia
- Dyspnea, chest pain, or tightness
- Hypotension/hypertension

Central Nervous System

- Severe headaches
- Trigger migraine headaches
- Aseptic meningitis*

Renal

- Azotemia
- Renal failure

Thromboembolic Events*

- Thrombosis/cerebral infarction
- Myocardial infarction
- Pulmonary embolism

Anaphylaxis From Anti-Immunoglobulin E (IgE) Antibodies to IgA

Other (Isolated Reports)

- Cardiac rhythm abnormalities
- Coagulopathy
- Serum sickness
- Hemolysis—alloantibodies to blood type A/B
- Cryoglobulinemia
- Neutropenia
- Alopecia
- Uveitis
- Noninfectious hepatitis
- Progressive neurodegeneration

*See text for predisposing risk factors.

including headache, stiff neck, and photophobia, usually develop within 24 hours after completion of the infusion and may last 3–5 days. Spinal fluid pleocytosis occurs in most patients. Long-term complications are minimal. The etiology of aseptic meningitis is unclear, but migraine has been reported as a risk factor and may be associated with recurrence despite the use of different IVIG preparations and slower rates of infusion. (Clinical Pearls 2)

Renal Adverse Events

Acute renal failure is a rare but significant complication of IVIG treatment and has been associated in the past with products containing sucrose. Histopathological findings of acute tubular necrosis, vacuolar degeneration, and osmotic nephrosis were suggestive of osmotic injury to the proximal renal tubules. Most patients (95%) had received large doses for treatment of autoimmune diseases. The majority of the cases were treated successfully with conservative therapy, but deaths were reported in 17 patients who had serious underlying conditions. Most cases of this adverse event were associated with IVIG products containing sucrose as a stabilizer. Risk factors for this adverse reaction include preexisting renal insufficiency, diabetes mellitus, dehydration, patient age >65 years, sepsis, paraproteinemia, and concomitant use of nephrotoxic agents. Newer IVIG products are using alternative stabilizers (*e.g.*, amino acids) instead of sucrose.

CLINICAL PEARLS 3

Risk Factors for Adverse Events

- Infusion issues
  - Prior history of an infusion reaction with an immunoglobulin (Ig) product
  - First infusion in a patient with active infection or inflammation
  - Changing immunoglobulin products
  - Rapid infusion and/or large dose
- Patient factors
  - Preexisting renal insufficiency
  - Prior history of thrombotic event
  - Autoimmune disorder
  - Diabetes mellitus
  - Age—older age
  - Hyperlipidemia or elevated cholesterol
  - Dehydration with volume depletion
  - Hypercoagulable state
  - Indwelling catheters
  - Paraproteinemia or other causes of hyperviscosity
  - Cardiac or peripheral vascular disorders
  - Estrogen use
  - Smoking

Thromboembolic Events

This adverse effect was observed mainly in patients receiving large doses of IVIG for autoimmune diseases. Patients with elevated serum viscosity (*e.g.*, cryoglobulinemia, hypergammaglobulinemia, and hypercholesterolemia) are at risk for developing a critical increase in serum viscosity with IVIG, especially high doses that predispose them to thromboembolic events, such as myocardial infarction, stroke, deep vein thrombosis, or pulmonary embolism. (Clinical Pearls 3) Recently, a contaminating procoagulant factor (*e.g.*, factor XIa) has been implicated in these thromboembolic events.[22] Patients at risk are older (>65 years), on multiple drugs, and have comorbidities, such as diabetes, hypertension, and so on. Patients at risk should be well hydrated, IVIG should be administered at lower rates, and products with low sodium and an osmolality in the physiological range should be selected. Ig manufacturers have taken steps to remove or reduce this procoagulant activity from their products.[23]

Transfusion Reaction Caused by Antibodies Against IgA

True anaphylaxis is rare in patients with selective IgA deficiency and CVID who develop IgE antibodies to IgA after treatment with Ig; this adverse event appears to be much less frequent than originally thought. Patients with CVID have IgG antibodies (10–22% in various studies) to IgA, but there is no correlation to the presence of these antibodies and adverse reactions.[24] Patients with anti-IgA antibodies who have had reactions to IVIG have tolerated SCIG.[25]

Other Adverse Reactions

A number of other adverse reactions have been reported in association with IVIG infusions. (Clinical Pearls 2) These side effects are usually less common and are discussed in more detail elsewhere.[21]

Summary: Ig Replacement in Treatment of Immune Deficiency

Ig replacement is the mainstay of treatment for primary humoral immune deficiency. The goal of treatment is to provide a broad spectrum of antibodies to prevent infections and chronic long-term complications. The usual dose is 400–600 mg/kg/month, but this may vary among individuals, and some patients may require higher doses. A serum trough level above 500 mg/dL has been shown to be effective in the prevention of serious bacterial infections. However, recent studies have suggested that even higher doses (*e.g.,* a “biological” trough level and achieving trough levels of IgG in the range of 750–900 mg/dL) may be desirable.[6] Ig can be given intramuscularly, intravenously, or subcutaneously. SC administration has been proven to be safe and is a good alternative in some patients, especially those experiencing side effects of administration by the IV route. Generally, IVIG replacement therapy is considered safe in the majority of patients. Side effects are usually mild and treatable with premedication. Good manufacturing practices, improved screening of plasma donors, testing of the source plasma, and additional viral inactivation and removal steps have made IVIG a better and safer plasma-derived product. To optimize the care of patients with PIDs, there are eight guiding principles for the use of Ig replacement therapy. (see Therapeutic Principles)

MECHANISMS OF ACTION OF IG THERAPY IN AUTOIMMUNE AND INFLAMMATORY DISEASES

Although we still do not understand *all* the mechanisms by which IVIG has immunomodulatory effects, knowledge of the actions of IVIG in these diseases will allow for definition of appropriate indications and schedules of administration of IVIG and the design of new-generation IVIG products that are better able to target the immune perturbations in autoimmune and inflammatory processes. (Key Concepts 3) Furthermore, additional multicenter placebo-controlled clinical trials are needed to confirm clinical efficacy. A more detailed discussion of the evidence-based treatment of autoimmune and inflammatory disorders can be found elsewhere.[1,2] This chapter will not review the indications for IVIG therapy; the reader is directed to other works, including comprehensive reviews and practice-based guidelines, for more details about the various indications for IVIG therapy in autoimmune and inflammatory disorders. This section will address the possible mechanisms of actions of Ig therapy; more than one mechanism(s) may be important in the immune modulation of these autoimmune disorders.

KEY CONCEPTS 3

Mechanisms of Action of Intravenous Immunoglobulin (IVIG) in Autoimmune and Inflammatory Diseases

- Blockade of Fc receptors on macrophages of the reticuloendothelial system of liver and spleen
- Restoration of idiotypic/antiidiotypic network
- Suppression or neutralization of cytokines by specific antibodies in the IVIG
- Block binding of adhesion molecules on leukocytes to vascular endothelium
- Inhibition of complement uptake on target tissues
- Neutralization of microbial toxins
- Blockade of Fas ligand mediated apoptosis by anti-Fas antibodies in the IVIG
- Induction of apoptosis with anti-Fas antibodies at high concentrations of IVIG
- Neutrophil apoptosis by anti-Siglec-9 antibodies in IVIG
- Saturation of FcRn receptors to enhance the clearance of autoantibodies
- Induction of inhibitory FcγInd receptors on effector macrophages
- Neutralization of growth factors for B cells (*e.g.,* B cell–activating factor ([BAFF])
- Inhibition of T-cell proliferative responses
- Expansion and/or activation of a population of regulatory T cells (Tregs)
- Enhancement of the cyclooxygenase 2 (COX-2) pathway by increasing prostaglandin E2 (PGE_2) from dendritic cells (DCs)
- Downregulation of the T-helper 17 (Th17) pathway
- Modulation of DC function through C-type lectin receptors (DCLRs) DC-specific intercellular adhesion molecule-grabbing nonintegrin (DC-SIGN; spleen) and DCLR (lung and lymph nodes)

Blockade of Fc Receptors of the Reticuloendothelial System

Idiopathic thrombocytopenic purpura (ITP) results from accelerated platelet destruction attributable to an immunological process resulting in bleeding that may be life threatening. Studies in ITP have shown that IVIG leads to the rapid reversal of the thrombocytopenia. Autoantibody-opsonized platelets are destroyed in the spleen and the liver by FcγR-mediated phagocytic clearance. (Key Concepts 4)

Interactions of Idiotype and Antiidiotype as Immune Modulation

Idiotype–antiidiotype interactions between antiplatelet glycoprotein IIb (GPIIb)/IIIa autoantibodies and IVIG may be another mechanism by which IVIG could affect autoantibody production and effector function in ITP and may be playing a role in the long-term immune effects in ITP. IVIG contains antiidiotypic antibodies to anti-DNA, anti–factor VIII, antineutrophil cytoplasmic antibody (ANCA) autoantibodies, antithyroid autoantibodies, and others. A proposed mechanism of action of IVIG in ANCA-positive vasculitis is binding or neutralization of the ANCA autoantibodies by antiidiotypic antibodies in IVIG. Studies have shown that IVIG contains antibodies with idiotypic specificities that can bind and neutralize potentially pathogenic autoantibodies in autoimmune neurological diseases, such as Guillain-Barré syndrome (GBS), chronic inflammatory demyelinating polyneuropathy (CIDP), and myasthenia gravis (MG).[26] Antiidiotypic antibodies in IVIG directed against idiotopes on the anti-GM_1 Ig molecule block the binding of the anti-GM_1 antibodies to its target antigen. Support for a similar mechanism in MG comes from the fact that IgG or $F(ab')_2$ fragments in IVIG preparations are capable of binding to anti–acetylcholine receptor antibodies *in vitro*. Additionally, using *in vitro* nerve-muscle preparations, Buchwald et al.[27] showed that the $F(ab')_2$ portion of IVIG neutralized the “blocking” effect of serum from patients with acute GBS. (Key Concepts 5)

These antiidiotypic antibodies may also act in concert with their effects on the FcγRIIB receptor on B cells to produce a negative "off signal" to the B cells synthesizing these autoimmune antibodies. Thus the antiidiotypic antibodies in IVIG may be beneficial by restoring the idiotypic control network in these autoimmune diseases.

The Role of the FcRn Receptor on Immune Modulation

The FcRn receptor (neonatal Fc receptor) was identified as the receptor responsible for protecting IgG from catabolism in the endocytic vesicles of the endosome, and this explains the relatively long half-life of this plasma protein. IVIG may accelerate the catabolism of IgG autoantibodies by saturating these protective receptors in direct proportion to the relative concentration of exogenous plasma levels of IgG from IVIG. In mouse models of bullous pemphigoid and arthritis, IVIG treatment resulted in a reduction in pathogenic antibodies to levels below the disease-causing threshold, and this effect was attenuated in FcRn-deficient mice.[28] Hansen and Balthasar[29] showed in a rat model of immune thrombocytopenia that IVIG enhanced the clearance of antiplatelet antibodies in a dose-dependent manner by saturation of the FcRn receptor. These same investigators[30] estimated that approximately 50% of the overall effect of IVIG in ITP may be attributed to IVIG-mediated acceleration of the elimination of antiplatelet antibodies by the FcRn saturation mechanism and showed that in FcRn knock-out mice, IVIG failed to increase the clearance of antiplatelet antibodies. However, very little data, if any, are available in human autoimmune disease to support this mechanism.

KEY CONCEPTS 4

Proposed Mechanisms of Action of intravenous immunoglobulin (IVIG) in Autoimmune Idiopathic Thrombocytopenic Purpura

- Fc receptor blockade of reticuloendothelial system
- Fcγ receptor downregulation
- Idiotype–antiidiotype interaction between antiplatelet GPIIb/IIa autoantibodies and the antiidiotypic antibodies in IVIG
- Activation of inhibitory receptor FcγRIIB
- Saturation of FcRn receptor to accelerate the catabolism of antiplatelet autoantibodies

Modulation of Immunoregulatory Function Through the Fc Receptor

The FcγRIIB receptor provides an inhibitory signal to cells through a pathway mediated by an immunoregulatory tyrosine-based inhibition motif (ITIM). Studies have shown that IVIG stimulates these inhibitory FcγRIIB receptors found on a variety of cell types, including macrophages, B cells, and a subpopulation of T cells. Samuelsson et al.,[31] using a murine model of ITP, showed that the administration of IVIG prevented platelet destruction by a pathogenic monoclonal autoantibody. Protection was associated with the induction of the expression of FcγRIIB receptors on splenic macrophages. This inhibitory FcγRIIB receptor was required for the protection of the animals against the monoclonal autoantibody, since disruption of the receptor by either genetic deletion or a blocking monoclonal antibody (mAb) reversed the therapeutic effects of IVIG. Kaneko et al.[32] showed that that the inhibitory properties of IVIG were linked to the sialylation of the glycan component of the Fc fragment. The important glycan moiety in the IgG molecule is located at the asparagine (Asn^{297}) site in the second domain of the constant region. Using a K/BxN serum-induced arthritis model in mice, Kaneko et al.[32] showed that IVIG at 1 g/kg inhibited the inflammatory arthritic process. Deglycosylated or neuraminidase-treated IVIGs were unable to inhibit this inflammation. IVIG enriched for the sialylated glycan moiety had comparable inhibitory effects on the inflammatory process at only one-10th of the dosage used with intact IVIG. This inhibitory activity was dependent on FcγRIIB expression on effector macrophages. Anthony et al.[33] engineered a recombinant/sialylated human IgG1 Fc protein that had 35-fold enhanced immune-modulating activity compared with native IVIG. Anthony et al.[34] performed studies to examine the mechanism by which the sialylated Fc fragment could mediate its antiinflammatory activity and to identify the target cell that initiates this antiinflammatory pathway. A splenic marginal zone macrophage expressing the C-type lectin receptor (*i.e.*, SIGN-R1) was required for the antiinflammatory activity of IVIG in concert with its ability to bind to sialylated Fc domains. These authors proposed that the interaction between sialylated IgG Fc and SIGN-R1 leads to the upregulation of the inhibitory FcγRIIB receptor on effector cells. They suggested that DC-SIGN (dendritic cell–specific intercellular adhesion molecule-grabbing nonintegrin), the human orthologue of SIGN-R1, has a comparable role in the antiinflammatory effects of IgG Fc fragment on human macrophages and dendritic cells (DCs). Anthony et al.[35] presented data in their murine model that this immune-modulating pathway may be mediated by the production of interleukin-33 (IL-33) by DCs, which, in turn, produce IL-4 from basophils, leading to the increased expression of the FcγRIIB receptor on effector macrophages. Of note, observations in patients with chronic inflammatory demyelinating polyneuropathy (CIDP) treated with high-dose IVIG demonstrated upregulation of the FcγRIIB receptor on peripheral blood monocytes.[36] Others, however, have questioned whether this pathway of immune modulation is important in humans.[37-39] Nevertheless, these exciting studies define, at least in mice, an important mechanism by which IVIG modulates immune processes mediated through sialylated Fc on the IgG molecule and the receptors on DCs and effector macrophages (*i.e.*, SIGN-R1 and FcγRIIB) involved in this antiinflammatory process.

KEY CONCEPTS 5

Proposed Mechanisms of Action of IVIG in Neuromuscular Diseases

- Modulation of proinflammatory cytokines, *e.g.*, TNF-GR α, IL-1GR β in GBS
- Reduction in muscle levels of ICAM-1, TGF-GR β, and TGF-GR β mRNA in dermatomyositis
- Neutralization by antiidiotypic antibodies in IVIG of potentially pathogenic autoantibodies, e.g., anti-Gm1 antibodies in GBS and CIDP, and anti-AchR in MG
- IVIG saturation of FcRn receptors to accelerate degradation of IgG autoantibodies
- Inhibition of complement deposition and formation of MAC on endomysial capillaries in dermatomyositis

AchR, acetylcholine nicotinic receptor; CIDP, chronic inflammatory demyelinating polyneuropathy; FcRn, neonatal Fc receptor; GBS, Guillain-Barré syndrome; MAC, membranolytic attack complex; MG, myasthenia gravis.

Neutralizing Antibody Activity in IVIG Against Bacterial Toxins

Kawasaki syndrome (KS), an acute multisystem disease of unknown etiology, primarily affects infants and young children. Although KS occurs worldwide in children of all racial groups, it is most prevalent in Japan and in children of Japanese ancestry. Although the acute illness is generally self-limiting, coronary artery abnormalities related to a generalized inflammation and immune activation of small- and medium-sized blood vessels develop in up to 25% of untreated patients. Although the etiology remains unknown, the clinical features and laboratory findings suggest an infectious or postinfectious process. The administration of high-dose IVIG, together with aspirin, is the standard of care in the treatment of KS.

KS is associated with marked activation of T cells and monocytes–macrophages. On the basis of immunological and clinical features of KS overlapping with those of bacterial toxic shock–like syndrome, studies were carried out to determine if KS is associated with exposure to a superantigen, such as a bacterial toxin. Acute KS is associated with marked immune activation and increased circulating cytokine levels. Some of these cytokines elicit proinflammatory and prothrombotic responses by inducing the expression of leukocyte adhesion molecules, which localize inflammatory cells to vascular endothelial cells. The expression of endothelial–leukocyte adhesion molecules has been demonstrated in acute KS, and its downregulation correlates with favorable response to IVIG treatment. The magnitude and persistence of proinflammatory cytokine synthesis have been reported to constitute a risk for the development of coronary artery abnormalities.

IVIG has been shown to contain high titers of specific antibodies inhibitory to the activation of T cells by staphylococcal and streptococcal superantigens (Chapter 6). These findings may account for the observation that treatment of acute KS with IVIG results in a marked reduction of macrophage and T-cell activation.[40] In this regard, the efficacy of IVIG in suppressing the immune activation associated with KS and, more importantly, its ability to prevent the development of coronary artery abnormalities in this illness may relate to the neutralizing antibody activity of IVIG against these bacterial toxins. Toxin neutralization is not likely the only beneficial effect of IVIG in KS. Blocking or neutralizing cytokines by the anticytokine antibodies in IVIG may modulate the local inflammatory responses of blood vessels in KS by modifying leukocyte adhesion after increasing the expression of cell-surface determinants on vascular endothelial cells.

IVIG may have therapeutic value in the treatment of patients with toxic shock syndrome secondary to *Staphylococcus aureus* or *Streptococcus pyogenes* exotoxins. In an open study by the Canadian Streptococcal Study Group[41], IVIG appeared to be beneficial in patients with streptococcal toxic shock syndrome. In a meta-analysis of IVIG treatment of neonatal sepsis, there was a sixfold decrease in mortality. IVIG inhibits *Staphylococcus* exotoxin–induced T-cell activation and contains antibodies against exotoxins responsible for toxic shock syndrome. Great variations in neutralizing activity against streptococcal pyrogenic exotoxins can be found in different brands and even among different lots of IVIG. However, these findings suggest that it is possible to select one IVIG preparation that contains high levels of neutralizing activity against a wide variety of Group A streptococcal superantigens, which could be used in the treatment of streptococcal toxic shock syndrome. The neutralizing capacity of IVIG against these bacterial superantigens is important because of their potential to stimulate the production of proinflammatory cytokines that lead to clinical disease. A number of *in vitro* studies have shown that IVIG can inhibit the production of, or bind to and neutralize, a number of cytokines and growth factors from various cell types.[42-44] Thus IVIG may exert its antiinflammatory effects in many different types of inflammatory diseases by interrupting or modifying a number of different steps in the inflammatory cascade, from the inhibition of effector cell function to reduction in cytokine-induced endothelial cell activation, or the “neutralization” of proinflammatory cytokines.

Modulation of Adhesion Molecules on Endothelial Cells and Antibodies in IVIG to Cell Surface Receptors

IVIG contains a number of natural autoantibodies that may have immune-modulating activities (*e.g.*, antibodies to CD4, major histocompatibility complex [MHC] class I molecules, cytokines, adhesion molecules, and Siglec molecules on leukocytes and other cell surface molecules). The “natural” antibodies in IVIG have also been shown to bind to a number of plasma and tissue proteins, including B cell–activating factor (BAFF), granulocyte macrophage–colony-stimulating factor (GM-CSF), liver antigens, and beta-amyloid peptide.[42,45] The binding of native IgG can be significantly increased by mild denaturing conditions (*e.g.*, mild pH treatment and cold ethanol precipitation used during the manufacturing of IVIG). St-Amour et al.[46] suggested that these commercial fractionation processes for IVIG could contribute to its therapeutic antiinflammatory effects.

Vassilev[47] showed that IVIG contains specific antibodies to a 10-peptide sequence, including the RGD (Arg-Gly-ASP) motif that is expressed in adhesion molecules on a variety of cell surfaces. Most integrins bind to this RGD sequence. Gill et al.[48] reported that IVIG inhibits leukocyte recruitment into inflammatory tissues by inhibiting selectin and integrin binding. In a mouse model of sickle cell vaso-occlusive crisis, IVIG was shown to inhibit neutrophil adhesion to the vascular endothelium, resulting in an increase in capillary blood flow and reversal of the vessel occlusion.[49] IVIG could modulate this cytokine-mediated endothelial cell activation by neutralizing the effects of the cytokines, inhibiting endothelial cell responses to the cytokines, or inhibiting the production of cytokines and growth factors. These mechanisms of IVIG may be playing an important role in preventing coronary artery abnormalities in patients with KS.

Toxic epidermal necrolysis (TEN) and Stevens-Johnson syndrome (SJS) are severe drug-induced skin diseases (reviewed in Letko et al.[50]). TEN results in apoptotic epidermal cell death, in which there is separation of large areas of the skin at the epidermal junction, producing the appearance of scalded skin. Keratinocyte apoptosis that precedes epidermal detachment is an early event in TEN. A number of drugs, including sulfonamides, anticonvulsants, and NSAIDs, can cause TEN and SJS. The mortality rate can be as high as 30%. Viard et al.[51] studied serum samples from patients with TEN and found that the sera of these patients had very high levels of soluble Fas ligand (sFasL). Keratinocytes normally express the death receptor Fas. The keratinocytes of patients with TEN also express very high levels of active Fas ligand. In their small pilot study, Viard et al.[51] administered IVIG (0.2–0.75 g/kg for 4 consecutive days) to 10 patients with TEN. In all 10 patients, the progression of skin disease was rapidly arrested within 24–48 hours, with rapid skin healing and no adverse effects. In *in vitro* studies, IVIG completely inhibited Fas-mediated keratinocyte apoptosis. This effect was related to the presence of naturally occurring Fas-blocking antibodies in IVIG, which inhibit Fas-mediated keratinocyte cell death.

Modulation of Complement Effector Function

The principal inflammatory mechanism in dermatomyositis (DM) is complement (C)-dependent microangiopathy with activation of C3 and deposition of the complement C5b-9 membrane attack complex (MAC) on the endomysial capillaries.[26,52] Basta et al. showed that IVIG can inhibit the uptake of C components on target tissues.[53] In patients with DM who were treated with IVIG, C3 deposition was reduced with corresponding decreases in complement expression on endomysial capillaries.[26,52] IVIG prevents the uptake of complement components and formation of the MAC on the endomysial capillaries in the muscle tissues of patients with DM. Consequently, IVIG allowed neovascularization to occur with reversal of the ischemic process, resulting in muscle tissue healing. This effect of IVIG on complement deposition may be relevant to other autoimmune neurological diseases, such MG, GBS, and CIDP, in which complement may be playing a role in the tissue damage.[26,52] Arumugam et al.[54] showed that IVIG protects the brain against ischemic injury mediated by complement in a mouse model of experimental stroke.

Effects of Ig on the Regulatory T-Cell Pathways

In a mouse model of multiple sclerosis (MS), IVIG has been shown to expand and enhance the function of FoxP3$^+$ regulatory T cells (Tregs)[55] while inhibiting the differentiation of T-helper 17 (Th17) and Th1 cells. This protective effect of IVIG was lost in mice that were depleted of Tregs.[56] These changes were independent of FcγRIIB and the Fc domain, since F(ab')$_2$ fragments led to similar changes in Th17 cells, Tregs, and clinical efficacy in this experimental allergic encephalomyelitis (EAE) model. Desialylated IVIG had the same immune-modulating effects as "native" IVIG.[57] Investigations by Trinath et al.[58] suggested that the mechanism by which IVIG induces Tregs was the enhancement of the cyclooxygenase 2 (COX-2) pathway via increased expression of prostaglandin E2 (PGE$_2$) from human DCs.

Kaufman et al. have extensively studied the effects of IVIG therapy in an ovalbumin-sensitized mouse model of asthma. They reported that IVIG markedly attenuated lung inflammation, decreased bronchial hyperresponsiveness to methacholine, and suppressed the Th2 pathway.[59] The draining pulmonary lymph nodes of IVIG-treated mice showed a significant increase in CD4$^+$CD25$^+$FoxP3$^+$ regulatory cells. IVIG-primed DCs on adoptive transfer to ovalbumin (OVA)–sensitized and challenged mice abrogated airway hyperresponsiveness and induced Tregs.[60] In their model system, Massoud et al.[61] reported that sialylated IgG bound to a novel C-type lectin receptor (*i.e.,* dendritic cell immunoreceptor [DCIR]) induced Tregs. Thus a number of studies have demonstrated the importance of the induction of FoxP3$^+$ Tregs by IVIG in modulating the autoimmune/antiinflammatory process. In contrast, Ig therapy in this murine model downregulated the Th-17 pathway.[62] In patients with KS and GBS, clinical improvement with IVIG therapy correlated with increased number and function of Tregs.[63,64]

Summary: IVIG in Treatment of Autoimmune and Inflammatory Diseases

Clearly, IVIG (IgG) has a number of immune-modulating effects and has been found to be an effective treatment for a wide spectrum of autoimmune and inflammatory diseases.[44,65] At present, IVIG is FDA approved for only a few autoimmune and inflammatory diseases. In autoantibody-mediated disease, the Fc domain appears to be the important IgG moiety that leads to immune modulation. The importance of sialylation of the Fc fragment remains controversial, as do the mediators involved (*e.g.,* IL-33 and IL-4). Differences in animal models, IVIG source, route and timing of the administration of the IVIG, mouse strain, and other variables may account for the differences in the experimental observations of laboratories. In T-cell mediated animal models of disease, such as EAE, there is strong evidence that there is upregulation of Tregs and inhibition of the Th17 pathway. These effects may be mediated by the F(ab')2 portion of the IgG molecule, and not the Fc domain. Furthermore, there is also controversy over the receptor on antigen-presenting cells (APCs), such as macrophages and DCs, which are involved in the immune-modulating process mediated by IVIG. In certain animal models, the SIGN-R1 (or in humans DC-SIGN) is important, and in other models (*e.g.,* murine asthma), a novel C-type lectin receptor (DCIR) appears to be important. These differences undoubtedly relate to the disease model. Two studies have demonstrated the importance of the PGE$_2$ pathway on IVIG-induced immune modulation mediated by the F(ab')2 portion of the IgG molecule. These observations may point to the possibility of alternative treatment regimens that employ the selective increase in PGE$_2$ in certain autoimmune or inflammatory disorders to increase Tregs and inhibit the production of certain cytokines. Further clarification in human disease models using *in vitro* human cells is important. These mechanisms are not mutually exclusive, and probably more than one mechanism is playing a role in the efficacy of Ig therapy in an autoimmune disease process. A better understanding of the pathogenic mechanisms involved in these diseases will undoubtedly lead to a more effective therapy with IVIG and more specific, modified forms of this biological product.

ON THE HORIZON

Translational Research Opportunities Related to Immunoglobulin Therapy

- Elucidation of mechanism(s) of action will lead to more precise bioengineered molecular products to treat autoimmune and inflammatory diseases.
- Clarification of the mechanisms of action of intravenous immunoglobulin (IVIG) in autoimmune and inflammatory diseases should lead to better understanding of the pathobiology of these diseases.
- Enhanced product purification—identification of the minor components in Ig products that may contribute to adverse reactions should lead to improved manufacturing processes and improved product tolerability for patients (*e.g.,* procoagulant factors, isohemagglutinins)
- Ig delivery—development of innovative approaches to the delivery of Ig products to patients to enhance safety and compliance.

MULTIPLE-CHOICE QUESTIONS

1. The BEST strategy for dosing of immunoglobulin (Ig) replacement therapy in patients with antibody deficiency diseases is by achieving a serum IgG level:
   A. Of 500 mg/dL
   B. Of 1000 mg/dL
   C. Of 200 mg/dL over baseline
   D. That minimizes the number of infections

2. Thromboembolic events associated with intravenous immunoglobulin (IVIG) therapy in autoimmune diseases is thought to be caused by:
   A. Osmolality of the product
   B. Sodium content
   C. Factor XIa
   D. IgA in the product

3. Which of the following receptors during IVIG treatment of autoimmune disease is enhanced on effector macrophages?
   A. CD25
   B. FcγRI
   C. FcγRIIB
   D. TACI

4. Which mechanism of action of IVIG is important in the rapid increase in platelet counts in patients with autoimmune thrombocytopenic purpura (ITP)?
   A. Saturation of the FcRn receptors
   B. Neutralization of cytokines
   C. Blocking the uptake of complement on platelets
   D. Blocking the Fc receptors on macrophages

85

Gene Therapy for Primary Immune Deficiency Diseases

Caroline Y. Kuo, Donald B. Kohn

Gene therapy as it is being applied for primary immune deficiencies (PIDs) represents an autologous hematopoietic stem cell transplant (HSCT), in which a patient's own stem cells are genetically corrected and transplanted back (Fig. 85.1). Thus, gene therapy for PID builds upon decades of experience using allogeneic HSCT from a healthy donor, where replacement of some or all of a PID patient's bone marrow hematopoietic stem cells (HSCs) with HSC from a healthy donor can be curative of the disease. Although initial efforts in gene therapy were not beneficial for the patients involved, there has been steady progress with the methods, and there is now clear-cut therapeutic efficacy using gene therapy/autologous HSCT for the three most commonly transplanted PIDs: severe combined immune deficiency (SCID), Wiskott-Aldrich syndrome (WAS), and chronic granulomatous disease (CGD)(Chapters 22, 34). Most gene therapy efforts to date have used **gene addition** methods in which a normal copy of the relevant gene is added to the patient's cells, usually using a viral vector. More recently, methods are under development to perform **gene correction**, using homologous recombination (HR) DNA repair of double-stranded breaks induced near the site of genome mutations by site-specific endonucleases.

KEY CONCEPTS

- Some severe primary immune deficiencies (PIDs) can be treated by transplantation of hematopoietic stem cells (HSCs), but this is optimal with a well-matched immune-compatible donor and may entail immune complications.
- Gene therapy using autologous HSCs that have been gene-corrected (either added or endogenously-corrected) may avoid the immune complications of allogeneic transplant and confer similar benefits.
- Stable gene addition to HSC can be done using integrating viral vectors, from retrovirus and lentivirus.
- Early-phase clinical trials have been performed by applying gene therapy to PIDs.
- Gene therapy using gamma-retroviral vectors led to immune reconstitution for several forms of severe combined immune deficiency, Wiskott-Aldrich syndrome and chronic granulomatous disease, but some patients developed leukoproliferative complications.
- More recent trials using safer vectors are continuing to yield clinical efficacy with good safety profiles.
- New techniques are being developed for precise gene editing in HSCs, which may allow application to a wider spectrum of PIDs.

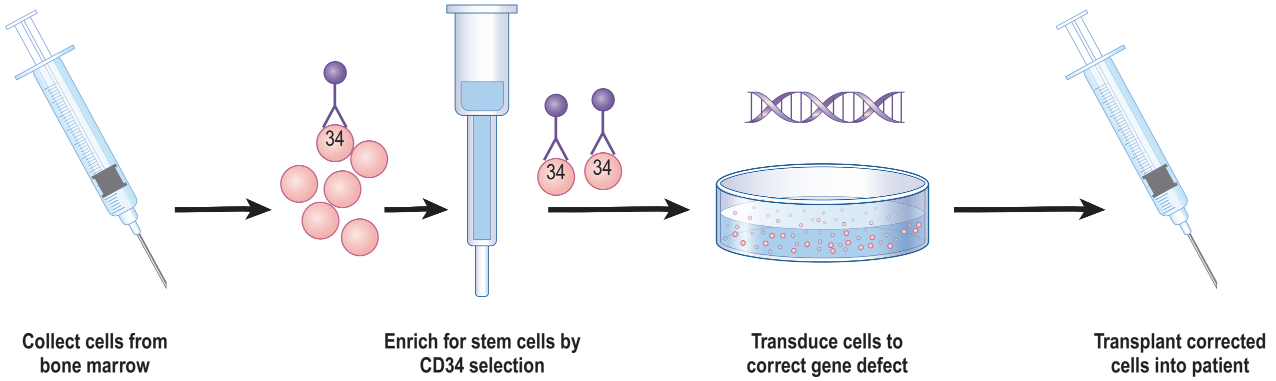
The key potential advantage of autologous transplant with gene therapy, compared to allogeneic HSCT, is that it may have reduced risks and a better safety profile, because it eliminates the need for pre-transplant immune-suppressive conditioning and post-transplant immune suppression; essentially, there should be no risk of graft-versus host-disease (GvHD) from the autologous graft (Table 85.1). Additionally, gene therapy could have increased efficacy compared to allogeneic HSCT in some conditions, due to the potential to over-express the relevant gene product (*e.g.* adenosine deaminase enzyme) and lead to a supra-physiological effect from the engineered graft.

However, gene therapy may have unique risks: the potential for the genetic manipulation of the genome of the stem cells by either gene addition or gene correction causing malignant transformation and leukoproliferative complications. Also, gene therapy could have decreased efficacy if the percentage of transplanted stem cells that are successfully gene-corrected is low, if the level of expression of the inserted transgene is suboptimal, or if the process of *ex vivo* gene manipulation impairs the stem cell's capacity for long-term hematopoiesis. Additionally, developing gene therapy for PID will require a separate research endeavor for each genetic etiology (*e.g.*, ADA SCID, XSCID, Rag1 SCID, Rag2 SCID, etc.), whereas allogeneic HSCT is a more "one size fits all" approach requiring less individualization for similar classes of disorders.

GENE TRANSFER TO HEMATOPOIETIC STEM CELLS

For gene therapy to have an enduring effect in PID, the gene addition or correction must occur in the long-term pluripotent HSCs by some method that will lead to the corrective gene being passed on to the billions of progeny blood cells made from each HSC. Gene modification of the far more numerous, but short-lived, progenitor cells would only lead to transient presence of gene-corrected blood cells. The technical challenge is for the gene delivery to HSCs to be efficient (high percentage of the cells modified), to yield persistent expression, and to have minimal immediate cytotoxicity or long-term genotoxicity.

Many of the gene transfer methods used for research purposes, such as transfection, electroporation, and nano-particle delivery are themselves transient, and the inserted gene would be lost by dilution as the stem cells proliferate. Thus, most of the studies to date have used viral vectors derived from the Retroviridae family that integrate their genomes into the chromosomes of the target cell to achieve persistence of the normal gene (Fig. 85.2). Genes delivered by murine gamma-retroviral, human lentiviral (HIV), spumaviral (foamy) or alpha-retroviral vectors remain permanently covalently linked to the cellular chromosomal DNA for stable transmission to progeny cells. The steps involved in using these types of vectors to produce a gene-modified HSC graft are described in the Therapeutic Principles box.



34
34
Collect cells from bone marrow
Enrich for stem cells by CD34 selection
Transduce cells to correct gene defect
Transplant corrected cells into patient

FIG 85.1 **Gene Therapy to Treat Primary Immune Deficiencies (PIDs) by Autologous Transplantation of Gene-Corrected Hematopoietic Stem Cells (HSCs).** HSC may be obtained from the bone marrow, by granulocyte–colony-stimulating factor (G-SCF) mobilization and leukapheresis (peripheral blood stem cells [PBSC]), or from umbilical cord blood of a PID patient. The HSC may be enriched by isolating the $CD34^+$ fraction of cells using immunomagnetic separation methods. The $CD34^+$ cell population is then cultured for gene manipulation (gene addition or gene correction). The gene-corrected autologous HSCs are then transplanted back to the patient.

TABLE 85.1 Advantages and Disadvantages of Allogeneic vs. Autologous (Gene Therapy) HSCT for PIDs

Transplant Type	Advantage	Disadvantage
Allogeneic HSCT	Normal function of relevant gene assured; benefit expected if sufficient donor chimerism	Need suitable matching donor
	Well-established and long-term experience with benefits/risks	Immune: GvHD and rejection risks.
	Excellent outcomes with matched sibling donor	Requires immune modulation: immune ablative conditioning; graft manipulation; and GvHD prophylaxis and treatment.
		May contribute to morbidity.
Autologous Gene Therapy HSCT	Patient is donor	Potential genotoxicity from gene addition or correction causing cell loss, dysfunction or transformation.
	No risks of GvHD.	Need to gene-modify high percentage of primary HSC with minimal toxicity.
	May not require immune suppression before (*e.g.*, flu/ATG) and after (*e.g.*, corticosteroids, calcineurin inhibitor) HSCT.	Low fractional correction may blunt efficacy.
	Risks of rejection may be less than with allogeneic cells.	Prior chemotherapy or marrow dysfunction may preclude use of autologous stem cells
	Transgene over-expression may have benefits (*e.g.*, adenosine deaminase).	Immunogenicity of transgene products is not well defined.
Gene Addition (*e.g.*, lentiviral vector)	Currently showing efficacy for SCID, WAS, and CGD (and for non-PIDs; *e.g.*, X-ALD, MLD, β-thalassemia).	Risks for insertional mutagenesis (gene disruption, gene activation) from semi-random insertions into target cell genomes.
	Current generation of SIN lentiviral vectors has significantly reduced genotoxicity, compared to earlier-used gamma-retroviral vectors.	Transgene not under normal transcriptional control. Function of transgene (level, lineage, longevity) may vary and be variegated.
Gene Correction (*e.g.*, nuclease/HDR)	Corrected endogenous gene should have normal function.	Risks of local or off-target gene disruption (insertion/deletion).
		Risk of translocations.

CGD, chronic granulomatous disease; *GvHD,* graft-versus-host disease; *HSC,* hematopoietic stem cells; *HSCT,* hematopoietic stem cell transplantation; *PID,* primary immune deficiencies; *SCID,* severe combined immune deficiency; *WAS,* Wiskott-Aldrich syndrome.

CLINICAL TRIALS OF GENE THERAPY FOR PRIMARY IMMUNE DEFICIENCIES

To date, clinical trials of autologous transplant/gene therapy have been performed for five PID disorders — multiple trials for ADA-deficient SCID, XSCID, CGD, and WAS, and one trial for leukocyte adhesion defect (LAD) (Table 85.2). These have occurred over roughly demarcated eras as the technology and clinical approaches advanced in the past three decades (Table 85.3). Because each genetic form of PID requires a separate development path from pre-clinical studies to define efficacy and safety through clinical trials, each individual PID will be discussed separately; although they share a common progression through the different eras.

Over these eras, the preferred vector for gene delivery to HSCs has progressed from murine gamma-retroviral vectors (γ-RV) to HIV-1–based lentiviral vectors in which the enhancers in the

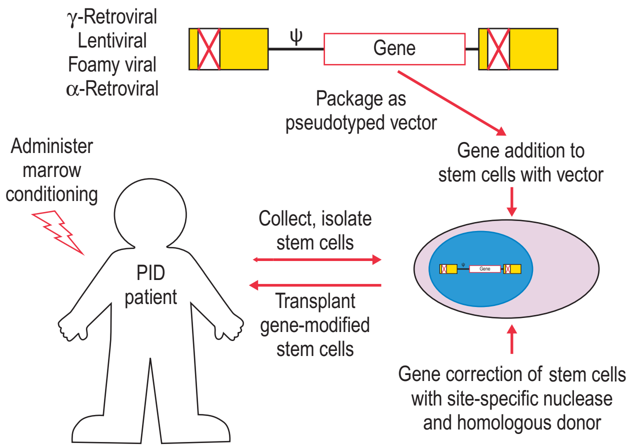

FIG 85.2 Autologous Transplantation of Gene-Corrected Hematopoietic Stem Cells (HSC). Gene addition may be performed using Retroviridae-derived vectors (from gamma-retroviruses, lentiviruses, foamy viruses or alpha-retroviruses) to transfer a normal copy of a relevant gene into HSCs collected and isolated from a primary immune deficiency (PID) patient. The gene-containing vector is packaged in a suitable envelope (pseudotyped) for gene addition to human HSC. Alternatively, the HSC may be gene-corrected using site-specific endonucleases to augment homologous recombination–directed gene correction. The patient may receive marrow cytoreductive conditioning to enhance engraftment after transplant of the gene-modified stem cells.

THERAPEUTIC PRINCIPLES

Steps for Gene Transfer to Hematopoietic Stem Cells for Clinical Transplantation

Package as Pseudotyped Vector

Transfect packaging cell with vector plasmid and virion/envelope plasmids.
Collect released vector from cell culture medium (DNAse).
Purify and concentrate vector (*e.g.,* ion-exchange chromatography, tangential flow filtration).
Aliquot. Certify. Release.

Transduce Stem Cells With Vector

Isolate CD34$^+$ stem/progenitor cells from clinical source (bone marrow, mobilized peripheral blood, cord blood).
Grow CD34$^+$ cells in serum-free medium plus recombinant cytokines (*e.g., ckit* ligand, flt-3 ligand, thrombopoietin).
Add vector to cells and culture for transduction.
Link vector sequences covalently into stem cell's chromosomal DNA.
Formulate and characterize cell product for release.

Administer Marrow Cytoreductive Conditioning

May deliver single or combination chemotherapeutic agents or monoclonal antibodies to "make space" in marrow.

Transplant Gene-Modified Stem Cells

Infuse gene-modified cell product intravenously.
Stem cells engraft and transmit transgene to all progeny blood cells.
Transgene produces necessary gene product to correct genetic deficiency.

long-terminal repeats are self-inactivated (SIN vectors). Lentiviral vectors have several potential advantages over γ-RV, including the ability to more effectively transduce human HSCs in a shorter period of *ex vivo* culture, the capacity to carry longer and more complex genetic sequences (such as cellular gene enhancers and promoters), and less tendency to insert near the 5′ ends of genes which may decrease risks for *trans*-activating expression of the adjacent cellular genes. The combination of recombinant cytokines used to activate the HSCs to facilitate transduction was advanced as factors were identified that acted on the earliest HSCs, including flt-3 ligand and thrombopoietin, combined with c-*kit* ligand.

Role of Cytoreductive Conditioning to Facilitate Engraftment

Initial trials of gene therapy for PID did not administer pre-transplant cytoreductive conditioning, due to potential risks of chemotherapy or radiation with unknown prospects of benefit from the gene transfer procedure. It is well-known from multiple transplant studies in mice and large animal models that there is minimal if any engraftment of autologous HSCs when given without prior conditioning, unless extraordinary numbers of cells (*e.g.*, 30–50x higher than standard cell dose/kg) are given; even mega-dose transplants without conditioning lead to only low levels of engraftment (*e.g.*, 1%), although this may be persistent.[1] While there was initial reluctance to use conditioning in gene therapy trials when there had not previously been efficacy, now with the clear-cut benefits that may be obtained from gene therapy, the necessity to use conditioning for autologous gene therapy HSCT (which is less than that needed for allogeneic HSCT) is becoming recognized as the standard. The amount and types of chemotherapy drugs used for conditioning has varied, depending on the disease setting. For SCID, where a relatively low level of gene-corrected HSCs may support immune reconstitution, reduced-intensity conditioning (RIC), such as relatively low dose busulfan alone (*e.g.* 4–6 mg/kg), may be sufficient. For other disorders where less of a selective advantage may exist for the gene-corrected cells, a higher level of engraftment of modified HSC may be needed, and thus stronger conditioning regimens have been used, reaching levels for myeloablative conditioning (MAC) (*e.g.*, busulfan, 12–16 mg/kg). For the WAS where it may be necessary to ablate the pre-transplant immunity to reduce risks for post-transplant autoimmunity, immune-suppressive drugs (*e.g.*, fludarabine, rituximab) have been added to conditioning regimens. These combined iterative approaches to improving gene therapy have led to the current state, where clinical benefits are being routinely achieved, as detailed below for each disorder.

New methods are being explored to "make space" in the marrow using alternatives to chemotherapy and radiation, such as monoclonal antibodies to markers present on HSCs. These are moving toward clinical assessments and may in the future facilitate engraftment with lower short-term and long-term risks than with chemotherapeutic agents.

Adenosine Deaminase (ADA)-Deficient Severe Combined Immune Deficiency (SCID; Chapter 35)

The first clinical trial of gene therapy for an inherited disorder (other than a premature attempt at gene therapy for beta-thalassemia) was directed against adenosine deaminase (ADA)-deficient Severe Combined Immune Deficiency (SCID). ADA-SCID was the first form of human SCID for which the responsible gene was identified and cloned, allowing gene therapy

TABLE 85.3 Eras in the Advancement of Clinical Gene Therapy for PIDs

Era	Predominant Vector	Growth Factors	Conditioning Regimen	PIDs Treated	Typical Outcomes
Early (~1990–1999)	γ-RV	IL3/IL6/SCF	None	ADA XSCID CGD LAD	Insufficient engraftment. No efficacy.
Middle (~1998–2006)	γ-RV	SCF/FLT3L/TPO	RIC-MAC	ADA XSCID CGD WAS	Efficacy. Genotoxicity in some.
Current (~2007–present)	SIN LV	SCF/FLT3L/TPO	RIC-MAC	ADA XSCID CGD WAS	Efficacy. Good safety profile.

to be approached.[2] As a ubiquitously-expressed housekeeping enzyme, the non-regulated expression of an introduced ADA gene was expected to be tolerated and potentially beneficial. Also, the ability to treat ADA-SCID with a bone marrow transplant from a matched sibling donor without the use of cytoreductive or immune suppressive conditioning was taken to imply that there is a selective advantage for ADA-replete T lymphocytes over ADA-deficient cells and that only a modest number of engrafted gene-corrected HSC may provide clinical benefit.

A series of clinical trials were performed using gamma-retroviral vectors and targeting either peripheral blood T cells or bone marrow hematopoietic stem cells. While initial studies in the early 1990's did not achieve clinical efficacy, subsequent trials that applied reduced-intensity condition prior to transplant to increase engraftment of gene-corrected HSCs have led to immune restoration in the majority of more than 40 treated patients, without vector-related complications.[3-6] The relatively low dose chemotherapy and absence of graft versus host disease makes these autologous transplants well-tolerated with essentially none of the clinical side-effects seen in allogeneic HSCT with conditioning. One of the retroviral vectors used in studies at Telethon Gene Therapy Program for Genetic Diseases, of the Hospital San Raffaele, in Milan Italy was licensed by GSK and has received licensure approval in the European Union, a major advance for gene therapeutics which is available for patients. Other ongoing clinical trials in the US and the UK are using a lentiviral vector for ADA SCID with excellent initial clinical results in terms of efficacy and safety. Thus, gene therapy for ADA SCID has become a major treatment option for patients, as the efficacy and safety profile have been favorable and may exceed those of matched unrelated or haplo-identical transplants, although there have not been randomized controlled trials.

X-linked SCID (Chapter 35)

The second genetic form of human SCID for which the relevant gene was identified and cloned is the X-linked form (XSCID).[7,8] The responsible gene, $IL2R_\gamma$, encodes the common cytokine receptor chain (or γ_c), a component of several multimeric receptors for a family of lymphopoietic cytokines: IL-2, IL-4, IL-7, IL-9, IL-15 and IL-21. Defects of γ_c severely impair the development of multiple components of the immune system and patients typically have severely reduced numbers of T and NK cells, and may have immature but non-functional B cells. Retroviral-mediated gene transfer of a normal human $IL2R_\gamma$ cDNA was shown to restore cytokine-induced signaling activity and lymphocyte function in patients' cells and in murine models.[9-12]

XSCID patients were first treated by gene therapy using gamma-retroviral vectors.[5,13] No conditioning was given, relying on the potent selective survival and proliferation advantage gene-corrected lymphoid cells were expected to have in lymphopenic SCID patients. Indeed robust reconstitution of T cell immunity was achieved, although there were variable responses of B cells. However, after 2-3 years from treatment, several of the patients developed a severe complication from the retroviral vector of leukemia-like leukoproliferation. New vectors were developed that lacked the strong enhancer elements of the retroviral vectors that caused the insertional oncogenesis (self-inactivating or "SIN" vectors). One published study using a SIN gamma-retroviral vector demonstrated immune restoration without any evidence of leukoproliferation. New studies are in progress using lentiviral vectors.[14] The first of these studies treated a group of XSCID patients who had undergone allogeneic transplant some years earlier, but who had not achieved complete immune reconstitution and had significant morbidity from poor growth and development.[15] Following gene therapy using a lentiviral vector and non-myeloablative conditioning, all have improved general well-being, with development of sufficient antibody production to be able to stop immunoglobulin replacement therapy. Studies treating more typical XSCID infants are now underway at several centers in the US and Europe. Thus, the ability of gene therapy to provide clinical benefit to these difficult patients is indeed gratifying.

Leukocyte Adhesion Defect (LAD; Chapter 22)

Bauer and Hickstein performed gene therapy for two LAD patients using a gamma-retroviral vector expressing human CD18 to transduce bone marrow cells without conditioning.[16] There were no beneficial effects of gene therapy and both later succumbed to complications of their immune deficiency. These investigators have developed a highly effective vector from the spumavirus called Human Foamy Virus and a clinical trial is under development.[17]

Chronic Granulomatous Disease (CGD; Chapter 22)

Chronic Granulomatous Disease (CGD) is a rare primary immunodeficiency (1 in 200,000 live births in the US), first termed Fatal Granulomatous Disease of Childhood in 1959 to describe individuals affected by recurrent, invasive bacterial and fungal infections complicated by granuloma formation.[18] Clinical presentation is explained by defects in any of the components that comprise the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex leading to phagocyte dysfunction. In its fully assembled form, the NADPH oxidase complex is composed of five proteins, two of which are membrane-bound (gp91phox and p22phox) and three of which are cytosolic (p47phox, p67phox, and p40phox). All five components are necessary for proper NADPH oxidase function without which affected individuals are particularly predisposed to infections with *Aspergillus* species, *Staphylococcus aureus*, *Burkholderia cepacia*, *Serratia marcescens*, *Nocardia* species, and less commonly, *Salmonella* and BCG infections outside of North America. Defects in gp91phox encoded by *CYBB* account for the most common X-linked form of CGD while the remaining defects are inherited in an autosomal recessive (AR) pattern.[19] Since its initial description almost six decades ago, CGD has evolved from a disease with early mortality to one with relatively good outcomes and multiple treatment options.

While prophylactic antimicrobial and immunomodulatory agents have dramatically decreased infection rates in CGD patients, curative therapy can only be achieved with HSCT. Transplant outcomes have continued to improve over the years, with good results reported even in patients with high-risk features such as intractable infections and auto-inflammation using reduced-intensity conditioning protocols.[13] Nevertheless, allogeneic HSCT can still be complicated by graft-versus-host disease and pre-existing infections and is not preferred for those without an HLA-matched stem cell donor. For these patients, autologous HSCT with gene-modified cells is becoming a more viable and realistic option.

The first gene therapy trials for CGD began in the mid-1990's again using gamma-retroviral vectors. As with ADA SCID, initial trials in which pre-transplant conditioning was not used did not lead to efficacy as there was minimal if any engraftment of gene-corrected stem cells. In subsequent studies where non-myeloablative conditioning with busulfan was used, increasingly higher levels of engraftment of corrected stem cells was achieved. The best and worst of these studies was one using a gammaretroviral vector with a potent transcriptional control element to drive high level expression of the *gp91phox* gene. The three treated subjects had initial development of neutrophils with restored oxidase function and cleared severe resistant infections. However, insertional oncogenesis occurred in this study also, and myelodysplasia or frank myeloid leukemia developed. More recently, trials are using a lentiviral vector with a myeloid-specific transcriptional control element intended to drive *gp91phox* expression in mature myeloid cells, where it is needed, but to not have activity in HSCs that are the likely targets for transformation. Initial results are showing safety and evidence of efficacy.[14]

Recently, the group at NIH has also investigated the use of site-specific endonucleases (a zinc-finger nuclease, discussed below) to target integration of a normal gp91phox cDNA expression cassette to the AAVS1 gene "safe harbor site".[15] Good levels of engraftment were demonstrated in mouse models, with up to 11% of human cell expressing gp91phox *in vivo*. This work represents the first step towards targeted gene editing for X-CGD and suggests that it can also be possible to integrate the transgene in its natural location in the genome under control of its endogenous promoter.

WISKOTT-ALDRICH SYNDROME (WAS; Chapter 35)

The Wiskott Aldrich Syndrome (WAS), initially described as an X-linked syndrome in kindreds in Germany and the US, presents with multiple clinical manifestations, including the classical triad of immune deficiency, eczema and thrombocytopenia. The complex immune deficiency involves defects of T, B, NK and antigen-presenting cells. The identified WAS gene encodes a 501 amino acid proline-rich protein that has multiple identified functional domains, placing it at the nexus of intracellular signaling and cytoskeleton control. Once the WAS cDNA was obtained, gamma-retroviral vectors were constructed and shown to correct several manifestations of the disorder in patient derived cells and in murine models. However, it is not fully known what levels of WAS transgene expression are needed to safely and effectively correct the major manifestations of lymphocyte and platelet dysfunction. A concern has been raised that sub-optimal levels or low frequency of expression of WAS protein (WASP) could allow auto-immunity to develop. If correction is only partial, (*e.g.*, some proportion of B cells are not gene corrected and have defective auto-regulatory function), auto-immunity may occur.[16]

A first trial of gene therapy for WAS used a gamma-retroviral vector with a very potent long terminal repeat promoter enhancer (from the Spleen Focus Forming Virus). G-CSF-mobilized peripheral blood stem cells were used as the HSC source and conditioning with myeloablative dosages of busulfan was given prior to transplant. There were excellent initial results in terms of immune reconstitution and platelet counts, demonstrating that gene therapy can be therapeutic for this disorder. However, there was subsequently a very high incidence of acute leukemia among these patients, developing within a few years from treatment, with ALL, AML or both occurring in a shocking 7 of 9 subjects.[17] The mechanism of insertional oncogenesis from the gamma-retroviral vector was clearly the cause, with the leukemias showing clonal vector integrations adjacent to known proto-oncogenes, such as *LMO2* and *MDS1*.

While that trial was being initiated, work was ongoing through a multi-center collaboration in the EU to develop a SIN lentiviral vector for WAS that uses the promoter from the WAS gene *per se* to drive expression of the WAS cDNA. Extensive pre-clinical studies showed the efficacy of this vector to improve immunologic and hematologic parameters in murine and human disease models.[18,19] And, it displayed significantly lower risks for genotoxicity than the type of gamma-retroviral vector used in the first trial.

The lentiviral vector with the WAS promoter has now been used in parallel but independent phase I/II clinical trials performed in several countries.[20,21] Relatively high intensity conditioning was administered to attempt to obtain high-level engraftment of gene-corrected HSCs, with some differences among the centers in the precise conditioning regimen used. All used moderate doses of busulfan (pharmacokinetically [pK]-adjusted) and fludarabine, and variably, rituximab or other serotherapy agents. These trials have uniformly demonstrated efficacy and safety. Findings have included clinical improvement in general health, bleeding incidents, and eczema, and as expected for an autologous transplant, no problems from graft versus host disease. Most have had good recovery of T, B, NK cell numbers and functions. However, there has been only modest and variable improvements for platelet levels (*e.g.* 20-60,000/uL), with evidence that higher transplanted dose of transduced cells led to higher platelet counts.[20] No new onset of auto-immunity has been reported, although in some cases pre-existing problems have persisted. In fact, decreases of indices of auto-immunity and improved B cell tolerance have been documented after gene therapy for WAS.[22] Polyclonal vector integration patterns were seen, with no reported development of clonal expansions or frank leukoproliferative complications. Integration site patterns resemble those seen in other trials using lentiviral vectors into human HSCs, with highly diverse vector integration sites and no predilection for cancer-related genes, significantly different than the pattern seen in the gamma-retroviral vector trials.

These results are promising and of significant clinical benefit and safety, but would be better if more normal levels of platelets could be achieved. It is possible that the level of expression of WASP from the WAS gene promoter in the lentiviral vector is inadequate to support normal platelet production or survival. If so, introducing more than one copy of the vector per cell could lead to higher levels of WASP and higher platelet counts. The WAS gene promoter that has been used as a regulatory element (a 1.6 kb fragment from the 5′ end of the gene) may be sub-optimal to drive sufficient expression; there may be other regulatory elements from the WAS genomic locus not included in the vectors that are needed for some essential aspect of expression (lineage, level, longevity). Astrakhan et al[23] reported that a lentiviral vector using a stronger internal promoter (a retroviral LTR) to drive the WASP cDNA led to better restoration of T and B cell activity in the WAS gene knock-out mouse model. Alternatively, the absolute number of gene-corrected HSCs engrafted may mediate the platelet levels and a higher percentage of transduced cells or higher numbers of gene-corrected cells may support higher platelet levels. Relative risks of multiple integrants versus a stronger promoter are not known. As for the other disorders discussed here, direct gene correction should yield normal, physiologic expression of the WAS gene.

GENE THERAPY CONSIDERATIONS FOR OTHER PID

Currently, a new development project is needed to bring gene therapy to clinical application for each individual PID-causing locus, such as the more than 20 human genes that may cause SCID, 5 or more CGD loci, several for Hemophagocytic Lymphoistiocytosis (HLP), X-linked lymphoproliferative disease (XLP), etc. Each gene and disease setting poses different challenges in terms of necessary gene transfer efficiency, level of expression, need for regulation of the transferred gene, safety considerations, and measurable end-points.

X-linked agammaglobulinemia (XLA; Chapter 34) is another logical disease to consider treating by autologous transplant with gene therapy, since normal B cell development from HSC with a normal Bruton tyrosine kinase (BTK) gene should correct the immune deficiency. Because of the good clinical effects from immunoglobulin replacement therapy for XLA and the toxicities from HSCT, especially from chemotherapy and GVHD, HSCT is rarely done for XLA patients. A few XLA patients have had allogeneic transplants from healthy donors and have developed B cell reconstitution.

Gene therapy studies in *BTK* gene knock-out mice have shown that it can lead to immune reconstitution, using lentiviral vectors with B lymphoid-specific promoters.[24,25] While no adverse effects were seen from constitutive expression of the *BTK* gene in these murine studies, these do not constitute formal toxicology studies which would be needed before clinical applications. It is likely that regulated expression of *BTK*, rather than constitutive, ubiquitous expression, is needed for highest efficacy and safety. In theory, lentiviral viral vectors using components of the *BTK* gene transcriptional regulatory sequences could yield vectors with the desired expression specificity. Alternatively, gene correction of the *BTK* gene, using the methods discussed below, could restore precise *BTK* expression regulation and may have the greatest safety profile.

Common Variable Immune deficiency (CVID) comprises the most common severe human PID (Chapter 34). While immunoglobulin replacement therapy can ameliorate the immune deficiency caused by hypogammaglobulinemia, the high rate of other clinical complications that CVID patients may experience necessitate new treatments. However, gene therapy requires knowing the responsible pathogenic gene, and has been limited to monogenic disorders. To date, a single gene defect has not been identified in the majority of patients with CVID. There are some known CVID genes, including *TNFRSF13B* (encoding TACI 8–10%), *TNFRSF13C* (encoding BAFF-R), COS, CD19, and MSH5, which in total may be responsible for 10–15% of all CVID patients. A separate gene therapy project would be needed to develop treatment for each causal gene, through the full spectrum from pre-clinical activities to clinical trial performance. And, because most of these known CVID-causing genes are involved in cell stimulation and signaling, they may require regulated, rather than ubiquitous, constitutive expression for safety. Because of these constraints, it is not currently possible to apply gene therapy for the majority of patients with CVID.

There has been growing recognition of numerous immune dysregulation and auto-inflammatory syndromes due to autosomal dominant gain-of-function mutations (*e.g.* STAT3, MEFV, IL-1, NFkB, interferon pathways).[26] The pathology attributed to blood cells (as opposed to those effects on other tissues) may be corrected by HSCT, and here too autologous transplant/gene therapy may have advantages over allogeneic. Gene modification of a patient's HSC by addition of a shRNA cassette or gene disruption using site-specific endonucleases may suppress expression of the dominant gene. And, direct correction of the pathogenic mutation could also be beneficial, as discussed below. It is likely that the gene modification would need to be efficient to yield a high fractional correction of the engrafting stem cells. In this setting, some pre-transplant immune suppression may be needed to ablate pre-existing auto-immunity. And, perhaps most challenging for gene therapy are the PIDs that also have major somatic or developmental problems, such as chromosomal abnormalities, ataxia-telangiectasia, and others. Here the gene therapy with the HSC may benefit that component of the disorder but would not address the others; systemic delivery of genes or delivery to the CNS is under study, but it is not yet sufficiently efficient for most clinical needs.

GENE CORRECTION (EDITING) FOR GENE THERAPY OF PID

A major paradigm shift in gene therapy is under way as methods to perform precise edits of cells' genomes are being developed. As an alternative to the semi-random insertion of normal copies of the relevant gene delivered by a viral vector, as discussed for all of the studies above, techniques are being established to either correct specific bases in the DNA, or to insert (or remove) gene sequences at specific sites by harnessing cellular DNA repair pathways. These DNA repair mechanisms normally correct the many double-stranded DNA breaks that occur during DNA replication or from environmental genotoxic agents (ionizing radiation, chemicals). To simplify a highly complex topic, there are two major DNA repair pathways for rejoining the sequences that flank a double-stranded DNA break: non-homologous end joining (NHEJ) and homologous recombination (HR). NHEJ reconnects the broken ends of the chromosomes in a way that often leads to insertion or deletion of DNA bases (indels) at the junctional site. This is, in essence, a mutagenic process and may be used to disrupt genes to knock-out their activity, examples being the HIV-1 co-receptor CCR5, dominant-active

FIG 85.4 Site-Specific Insertion of a cDNA to Override Down-Stream Gene Mutations. A prototypical gene is shown with 5 exons (yellow boxes 1–5) and an upstream promoter (red box). A mutation in exon 2 (black X) inactivates the gene. A sequence-specific endonuclease (red arrow) is designed to introduce a double-stranded DNA break, in this case in the 5′ untranslated region of the gene (blue and green lines). A cDNA molecule contains the contiguous exons of the gene (orange 1–5), codon-optimized to increase expression and to eliminate homology with the endogenous exons to eliminate illegitimate recombination events, and a polyadenylation signal (pA) to terminate transcription. The cDNA is flanked by the sequences from the endonuclease cleavage site (blue and green lines). The donor can be inserted into the nuclease target site by homologous recombination, placing the cDNA under transcriptional control of the endogenous gene promoter; the cDNA transcript (red arrow) would override any downstream mutations in the gene.

transcriptional factors such as CTLA-4, or STAT3 Gain of Function alleles, a transcriptional repressor of fetal hemoglobin, etc. There have been clinical trials for patients with HIV infection in which the gene for CCR5 HIV co-receptor was disrupted using a zinc finger nuclease (ZFN) to make a double stranded DNA break while NHEJ was allowed to repair the break, leading to indels that inactivated the gene and co-receptor expression.[27]

HR is a more precise repair mechanism that normally uses a copied sister chromosome or the other homologue as a template to repair the break; sequences of the template are copied into the repair site and if there are differences, the template acts as a donor for the new sequences. For gene correction, an artificial donor template is provided to the cells to instruct the introduction of the intended sequence changes (Fig. 85.3). Beyond its use for modification of single base pairs, as illustrated here, HR can be used to introduce whole gene sequences into the target site by flanking a gene cassette with "homology arms" that consist of the DNA sequences homologous to the target site (Fig. 85.4).

Although HR has been used to introduce genes into cells, such as murine embryonic stem cells to make gene knockout and knockin mice, it is generally a low-frequency event (occurring in $1/10^6$–$1/10^4$ cells) and requires the use of selectable markers to isolate the rare desired recombinant. Whereas cloning and expansion of murine (and human) embryonic stem cells can be done to produce populations of the rare recombinant cells, this is not possible with primary HSCs, which cannot be expanded to any great degree from single cells. Methods achieving high efficiency of gene modification with low cytotoxicity in large numbers of primary stem cells are needed for clinical applications to autologous HSCT. The major breakthrough in this area comes from the observation that HR is vastly more frequent when a double-stranded DNA break is introduced close to the target site;[28] then, the repair donor molecule can be used at efficiencies in the range ~1–50% of treated cells.

Several classes of designer site-specific endonucleases have been derived, including ZFN, introduced above; Transcription Activator-Like Effector Nucleases (TALENs); and more recently Clustered, Regularly Interspaced, Short Palindromic Repeats (CRISPRs) that allow the introduction of a double-stranded DNA break at unique sites in the mammalian genome with high specificity. Current methods introduce the nuclease into HSCs in a method where it will only be present transiently, such as electroporation of *in vitro* transcribed messenger RNA encoding the nuclease proteins. The homologous donor template is introduced as either a short (*e.g.* 50–100 bases) single-stranded deoxy-oligonucleotide that is co-electroporated with the nuclease, or as a longer sequence carried by a viral vector that does not integrate into the target cell chromosome, including adeno-associated virus (AAV) or an integrase-defective lentiviral vector (IDLV). The development and application of this technology has evolved at an incredibly rapid pace and is approaching the levels of efficiency needed for clinical applications.

One caveat is that potential off-target activity of the nucleases could cause genotoxicity from either disruption of unintended genes or even introduction of chromosomal translocations between two cut sites produced simultaneously, *e.g.*, one on-target and one off-target. Current studies are assessing the consequences of this potential genotoxicity in human HSCs, while ongoing work is seeking to improve the specificity of the nucleases to eliminate or greatly minimize off-target activity.

Gene correction will have several advantages over gene addition. It would avoid the potential problems from randomly inserting vectors that may disrupt or over-stimulate adjacent cellular genes, as discussed above for the retroviral vectors. Crucially, correcting the endogenous gene keeps its expression under normal physiological control. This will be essential for gene therapy of many PIDs, where it could be problematic if the gene is expressed constitutively from a viral vector. For example, it was shown that retroviral vector delivery of a normal CD40 ligand gene corrected murine models of X-linked hyper-IgM syndrome (XHIM), but it subsequently led to the development of lymphomas in the mice from constitutive rather than regulated CD40 ligand expression.[29] Bruton tyrosine kinase (BTK), defective in X-linked agammaglobulinemia, similarly may need to be expressed specifically at certain stages of B-lymphocyte development for safety and efficacy. A long list of other loci involved in PIDs may similarly be best approached by gene correction, including SLAM, XIAP, JAK3, FOXP3, IL-10, IL7Ralpha, TACI, CTLA4, etc. While current gene correction techniques are likely below the frequency of efficiency needed to yield clinical benefits for most disorders, this field is moving at a lightning pace with new advances being reported weekly in the activity and specificity of a whole host of nucleases and other genome editing tools.

USE OF PLURIPOTENT STEM CELLS AS A SOURCE OF HSC FOR GENE THERAPY OF PID

The establishment of human pluripotent stem cells (hPSCs), initially as human embryonic stem cells (hESCs) and subsequently as induced pluripotent stem cells (iPSCs), has brought the promise of novel models to study human diseases (“disease in a dish”) and to provide renewable sources of patient-compatible cells for cellular therapies. The essentially unlimited ability to expand hPSCs and their capacity to produce any of the cell-types in the body has led to investigations to harness them for regenerative medicines. In the treatment of PIDs, hPSC could provide an ideal target to produce autologous HSCs with precise gene correction. While techniques have been developed to perform the gene modification strategies that may be sufficiently robust for clinical applications, the major roadblock is the current inability to produce clinically-relevant numbers of transplantable HSCs from hPSCs. The HSC is a relatively evanescent state and it has not been possible to “freeze” differentiation from hPSC at that state, although it has been possible to proceed right through the HSC stage to produce relatively pure populations of individual mature blood cells. As with gene correction, the pace of scientific progress with these phenomenal cells is proceeding rapidly, and it is likely that new sources of gene-corrected autologous HSCs will be available for clinical transplants in the near future.

GENE THERAPY FOR PID INVOLVING SERUM PROTEIN DEFICIENCIES

Whereas many of the severe PIDs are due to blood cell defects and thus responsive to HSCT, others result from deficiencies of serum proteins, such as complement components. Here, gene therapy may be approached, as is being done for hemophilia, by direct *in vivo* administration of a gene-containing vector that can permanently insert the gene into target tissues–such as the liver, skeletal muscle, or endothelium–that can serve as protein sources. *In vivo* gene delivery is being studied using retroviral and lentiviral vectors or adeno-associated virus (AAV) vectors, and methods for *in vivo* gene correction using site-specific nucleases and homologous donor sequences are also under development. To this end, Crystal and co-workers have recently reported studies in a murine model of hereditary angioedema using an AAV vector to express the *SERPING1* gene encoding the C1 inhibitor.[30]

ADVANCING GENE THERAPY FOR PID FROM EXPERIMENTAL TO STANDARD OF CARE

Initial trials of gene therapy for PIDs were all performed at tertiary-level academic medical centers, often with federal or disease-foundation research grant funding, and they tested initial hypotheses concerning safety and efficacy. These centers may continue to perform early phase clinical trials for specific disorders, especially where there is local expertise on the disease being studied. However, there is an ongoing transition to industry-sponsored trials focused on drug product development, as the effective vectors and the gene-modified stem cell products they compose are advanced to licensure and marketing as pharmaceutical agents. A common model used by these new gene therapy companies is one of central processing, at one or a few high-grade commercial GMP facilities. The autologous patient cells are procured at their home institution (by leukopheresis or bone marrow harvest), shipped to the central processing site for genetic manipulation and cryopreservation, and then returned to be administered locally. Currently, gene therapy transplants have been performed at a limited number of clinical trial sites due to the cell processing expertise needed; presumably under the commercial model, it may be done at any suitable hematopoietic stem cell transplant center, with the company selling the processed cell product, like a medical device or an unrelated stem cell product. Alternatively, self-contained cell processing and manipulation devices are being developed that could allow gene modification of stem cells to be done at individual institutions, without requiring highly trained staff or high-grade GMP facilities.

Major issues remain to be determined about cost and reimbursement for gene therapy. Effective gene therapy for the severe diseases being approached would be expected to lead to large lifetime savings in medical costs. The one-time price can be compared to the costs faced by the patient encumbered by the progressive nature of the underlying disease, to the costs for long-term protein-based therapies and possibly even to the costs for allogeneic transplantation. However, those one-time costs will be expensive for clinical gene therapy transplants using pharmaceutical-grade vectors and commercial-level cell processing with the attendant quality control. Thus, a single large expenditure for gene therapy may eventually be cost-effective compared to ongoing medical costs; however, the method of financing the large up-front charge, at least in the United States with its multiple insurance companies, remains to be determined.

CONCLUSION

In the past decades, gene therapy for PIDs has gone from a dream for the future to a clinical reality. Gene therapy for ADA-deficiency SCID has been safe and effective in most treated patients. Although initial trials of gene therapy for XSCID, CGD and WAS showed efficacy, they were marred by an unacceptably high rate of complications from genotoxicity associated with gamma-retroviral vectors. New vectors are now in clinical trials and are showing excellent safety profiles and higher efficacy in clinical trials for ADA-deficient SCID, XSCID, WAS, and CGD as well as other non-PID disorders. Approaches to direct gene correction are being developed that may broaden indications for PIDs that may be treated by gene therapy (*e.g.*, XHIM, XLA, etc.). Thus, the continued efforts of scientists and physicians to develop gene therapy are leading to a new therapeutic modality, ideally to permanently and safely cure these diseases.

ON THE HORIZON

- Continued expansion of the genetic types of PID being treated by gene addition using integrating vectors (*e.g.* other forms of SCID, other forms of CGD, LAD, HLH, etc.).
- Development of safe and effective marrow conditioning regimens that are not chemotherapy-based (*e.g.* monoclonal antibodies)
- Application of gene editing to broader spectrum of PIDs: *e.g.* X-linked agammaglobulinemia, X-linked Hyper-IgM syndrome (CD40 ligand deficiency), RAG1-deficient SCID, Gain of Function STAT1, IPEX).
- Understand the molecular pathogenesis of more PID (*e.g.* CVID, autoimmune) and develop effective gene therapy approaches. (Some may require more than just HSC correction, *e.g.* ataxia telangiectasia).
- Production of autologous HSC by cellular reprogramming coupled to effective expansion of HSC

MULTIPLE-CHOICE QUESTIONS

3-5 multiple choice review questions - these questions should have explanations for the correct answer.

1. Which of the following vector types is effective for high efficiency permanent gene addition to hematopoietic stem cells:
   A. Adeno-associated virus (AAV)
   B. Gamma-retroviral
   C. Plasmid – by transfection or electroporation
   D. Lentiviral
   E. Adenovirus
   1. A, B, C
   2. B and D
   3. A-D
   4. All are correct

2. Which of the following primary immune deficiencies have shown good clinical responses to gene therapy:
   A. Wiskott-Aldrich Syndrome (WAS)
   B. X-linked Severe Combined Immune Deficiency (XSCID)
   C. X-linked Chronic Granulomatous Disease (XCGD)
   D. X-linked Agammaglobulinemia (XLA)
   E. Common Variable Immune Deficiency (CVID)
   1. A, B, C
   2. B and D
   3. A-D
   4. All are correct

3. Which are true about gene editing:
   1. Gene editing may be preferred to gene addition for primary immune deficiencies where the relevant gene needs to be expressed under precise regulation.
   2. Cells can repair double-stranded DNA breaks by two predominate methods: Non Homologous End Joining (NHEJ), which tends to introduce insertions and deletions (indels) at the chromosome repair junction, and Homologous Recombination (HR), which can copy genetic information from a homologous donor sequence into the repair junction.
   3. The first human clinical trial using gene editing disrupted the gene encoding an essential HIV-1 co-receptor protein in autologous T cells.
   4. The introduction of a double-stranded DNA break increases the frequency of homologous recombination for site-specific gene editing.
   5. Gene editing methods can site-specifically disrupt, correct or introduce a gene.
      1. A, B, C
      2. B and D
      3. A-D
      4. All are correct

Glucocorticoids

Anthony J. Frew

Glucocorticoids (GCs) are among the most commonly prescribed drugs and are used for a wide range of medical conditions.[1] More than 60 years after their introduction into clinical practice, they remain the most important and most frequently employed class of antiinflammatory drugs, and their use continues to increase, with about 10 million new prescriptions issued for oral GCs each year in the United States.[2] Community survey data suggest that 0.5% of the general population and 1.75% of women aged over 55 years are taking oral GCs.[3,4] About 56–68% of patients with rheumatoid arthritis (RA) are treated more or less continuously with GCs.[1] Although GCs are relatively inexpensive, total market volume is valued at ≈US$10 billion per year.[2]

GCs are widely used because they are the most effective (and cost-effective) antiinflammatory and immunomodulatory drugs available. However, GCs can cause serious adverse effects, especially when used incorrectly.

MECHANISMS OF ACTION

The way that GCs are used in different clinical conditions is essentially empirical, as there is only limited evidence to support current practice in specific clinical settings.[1] In general, GC dosages are increased in parallel with the clinical activity and severity of the disease under treatment. The rationale for this approach is that higher dosages increase GC receptor saturation in a dose-dependent manner (Table 86.1), which intensifies the therapeutically relevant, genomic actions of GCs. Moreover, with increasing dosages, additional and qualitatively different, nonspecific, nongenomic actions of GCs come into play (see Table 86.1).

KEY CONCEPTS

Characteristics Applying to Genomic Actions

- Physiologically relevant
- Therapeutically effective at all dosages, even very small ones (low dose therapy).
- Slow; significant changes in the regulator protein concentrations are not seen within less than 30 minutes because of the time required for cytosolic glucocorticoid receptor (cGCR) activation/translocation, transcription, and translation effects.
- The glucocorticoid (GC)–induced synthesis of regulator proteins can be prevented by inhibitors of transcription (*e.g.,* actinomycin D) or translation (*e.g.,* cycloheximide).

Genomic Actions of Glucocorticoids

The antiinflammatory and immunomodulatory effects of GCs are mainly mediated by genomic mechanisms (Figs. 86.1 and 86.2). Their lipophilic structure and low molecular mass allow GCs to pass easily through the cell membrane and bind to cytosolic glucocorticoid receptors (cGCRs). Ultimately this either induces the synthesis of regulatory proteins (“transactivation”) or inhibits their synthesis (“transrepression”).[5] About 10–100 genes per cell are directly regulated by GCs, but many other genes are regulated indirectly through interaction with transcription factors and coactivators (see below).[6] It has been estimated that GCs influence the transcription of approximately 1% of the entire genome.

Structure of the Cytosolic Glucocorticoid Receptor

The nonactivated cGCR (cGCRα) is a 94-kilodalton (kDa) protein held in the cytoplasm as a multiprotein complex, consisting of several heat shock proteins (hsps), including hsp90, hsp70, hsp56, and hsp40 (chaperones) (Fig. 86.3). The cGCR interacts with immunophilins, p23, and several kinases of the mitogen-activated protein kinase (MAPK) signaling system, including Src, which also act as molecular (co)chaperones (see Figs. 86.1 and 86.3).[1,7] The general function of molecular (co)chaperones is to bind and stabilize proteins at intermediate stages of folding, assembly, translocation, and degradation. With regard to cGCR, they also regulate cellular signaling, which includes *(i)* stabilizing a high-affinity conformational state of cGCR; *(ii)* opening the GC-binding cleft to be accessed by GCs; and *(iii)* stabilizing the binding of the GCR to the promoter.[1]

The first step in assembling the multiprotein cytosolic complex is adenosine triphosphate (ATP)–dependent and hsp40(YDJ-1)–dependent formation of a cGCR–hsp70 complex that primes the receptor for subsequent ATP-dependent activation by hsp90, Hop, and p23.[8] The GCR consists of different domains with distinct functions: an N-terminal domain; a DNA-binding domain (DBD); and a ligand-binding domain (LBD) (see Fig. 86.3). The N-terminal domain serves transactivation functions, especially within the “τ1” region. A zinc finger motif, a sequence common to many DNA-interacting proteins, is found twice within the DBD. The LBD consists of 12 α helices, several of which help form a hydrophobic ligand-binding pocket.[7] The cGCR contains another major transactivation region (“τ2”) that can interact with the above-mentioned cofactors (see Fig. 86.3). Following

TABLE 86.1 **Current Knowledge on the Relationship Between Clinical Glucocorticoid (GC) Dosing and Cellular GC Actions**

Terminology (Mg Prednisone Equivalent Per Day)	Clinical Application	Genomic Actions (Receptor Saturation)	Unspecific Nongenomic Actions	Cytosolic Glucocorticoid Receptor (cGCR)–Mediated Nongenomic Actions
Low dose (≤7.5)	Maintenance therapy for many rheumatic diseases	+ (<50%)	–	?
Medium dose (>7.5 – ≤30)	Initially given in primary chronic rheumatic diseases	++ (>50% – <100%)	(+)	(+)
High dose (>30 – ≤100)	Initially given in subacute rheumatic diseases	++(+) (almost 100%)	+	+
Very high dose (>100 mg)	Initially given in acute and/or potentially life-threatening exacerbations of rheumatic diseases	+++ ([almost] 100%)	++	+(+?)
Pulse therapy (≥250 mg for 1 or a few days)	Particularly severe and/or potentially life-threatening forms of rheumatic diseases	+++ (100%)	+++	+(++?)

FIG 86.1 **Mechanisms of the Cellular Action of Glucocorticoids (GCs).** As lipophilic substances, GCs pass very easily through the cell membrane into the cell, where they bind to ubiquitously expressed cytosolic glucocorticoid receptors (cGCRs). This is followed by either the classic cGCR-mediated genomic effects (1) or by cGCR-mediated nongenomic effects (2). Moreover, the GC is very likely to interact with cell membranes, either specifically via membrane-bound glucocorticoid receptors (mGCRs) (3) or via nonspecific interactions with cell membranes (4). (From Buttgereit F, Straub RH, Wehling M, Burmester GR. Glucocorticoids in the treatment of rheumatic diseases. An update on mechanisms of action. Arthritis Rheum 2004;50:3408–17.)

GC/cGCR binding, the hsp90 molecules and other molecular chaperones are rapidly shed. This allows translocation into the cell nucleus, where the GC/cGCR complex binds as a homodimer to consensus palindromic DNA sites (glucocorticoid-responsive elements [GREs]).[5]

Translocation Into the Nucleus

Nuclear translocation of the GC/cGCR complex occurs within 20 minutes. This may be caused by hormone-directed recruitment of FKBP52 and dynein to the GCR.[9] Depending on the target gene, transcription is then either activated (transactivation via positive GRE) or inhibited (transrepression via negative GRE).

Interactions With Transcription Factors

As well as the interactions of GC/cGCR complexes with GRE, a further important genomic mechanism of GC action is the interaction of activated cGCR monomers with transcription factors. Accordingly, although the GC/cGCR complex does

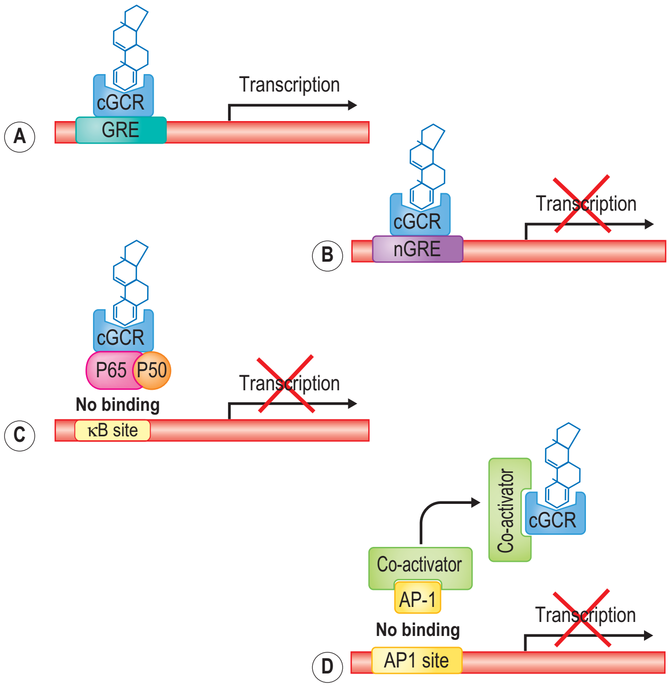

FIG 86.2 **Genomic Mechanisms of Glucocorticoids (GCs).** This figure illustrates the different mechanisms by which the activated glucocorticoid receptor (GCR) complex leads to the induction or to the inhibition of transcription and finally translation/synthesis of specific regulator proteins. Details are given in the text. (From Buttgereit F, Straub RH, Wehling M, Burmester GR. Glucocorticoids in the treatment of rheumatic diseases. An update on mechanisms of action. Arthritis Rheum 2004;50:3408–17.)

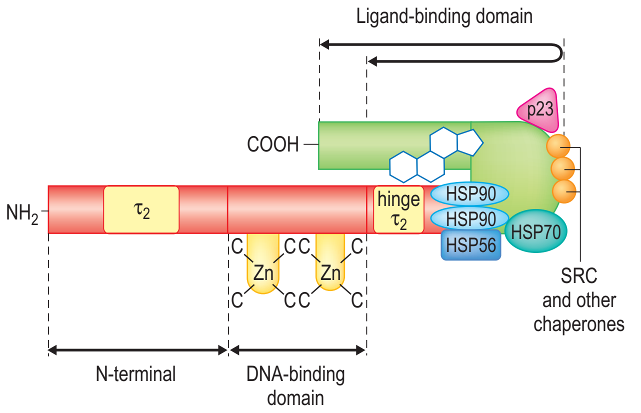

FIG 86.3 **Structure of the Cytosolic Glucocorticoid Receptor (cGCR).** The nonactivated (unligated) cGCR is a 94-kilodalton (kDa) protein retained in the cytoplasm as a multiprotein complex consisting of several heat shock proteins (hsps), including hsp90, hsp70, hsp56, and hsp40 (chaperones). Furthermore, the cGCR interacts with immunophilins, p23, and several kinases of the mitogen-activated protein kinase (MAPK) signaling system, including Src, which also act as molecular (co)chaperones. An important function of molecular (co)chaperones is to stabilize a specific conformational state of the GC which binds ligand with high affinity (see text). The receptor protein itself consists of different domains: an N-terminal, a DNA-binding domain (DBD), and a ligand-binding domain (LBD). The N-terminal harbors transactivation functions, especially within the so-called τ1 region. Another major transactivation region is τ2, which can interact with the above-mentioned cofactors. (From Buttgereit F, Straub RH, Wehling M, Burmester GR. Glucocorticoids in the treatment of rheumatic diseases. An update on mechanisms of action. Arthritis Rheum 2004;50:3408–17.)

not inhibit their synthesis, it modulates the activity of AP-1 (activator protein-1), nuclear factor (NF)-κB (nuclear factor-κB) and NFAT (nuclear factor for activated T cells). This leads to inhibition of nuclear translocation and/or function of these transcription factors and, thus, to inhibition of expression of many immunoregulatory and inflammatory cytokines. Possible mechanisms include[5]:

- Synthesis of IκB (a specific inhibitor of NF-κB) induced through GC/cGCR complex–GRE interaction (see Fig. 86.2A)
- Protein–protein interaction of the GC/cGCR complex with transcription factors through binding to their subunits (see Fig. 86.2C), which prevents their DNA binding
- Competition for nuclear coactivators between the GC/cGCR complex and transcription factors (see Fig. 86.2D)

Inhibition of transcription factor function and the resultant inhibition of protein expression are referred to as *transrepression.* Numerous genes are regulated by this mechanism. Many adverse effects of GCs are caused by *transactivation* (induced synthesis of regulator proteins), whereas most antiinflammatory effects are mediated by transrepression (inhibited synthesis of regulator proteins). This differential molecular regulation underlies current drug-discovery programs aimed at developing dissociated cGCR-ligands.[2]

The cGCRβ Isoform

The cGCRβ isoform is an alternative splicing variant of cGCRα that does not bind GCs or activate gene expression. This isoform is thought to function as a negative inhibitor of cGCRα, and it may play a role in the clinical phenomenon of GC resistance. cGCRβ lacks the GC-binding domain that is needed for activation, and as it does not undergo ligand-dependent downregulation, it has a longer half-life than the active form (cGCRα). It is thought that the likely mechanism of the dominant negative activity of cGCRβ is through the formation of inactive heterodimers with cGCRα.[10]

Posttranscriptional and Posttranslational Mechanisms

GCs also act through posttranscriptional and posttranslational mechanisms, including reduction of the half-life of cytokine messenger RNA (mRNA) and downregulation of the GCR, via reduced mRNA levels and reduced stability of the GCR protein.

KEY CONCEPTS

Glucocorticoid (GC) Effects on Immune Cells

- Inhibit leukocyte traffic and access of leukocytes to the site of inflammation
- Interfere with functions of leukocytes, fibroblasts, and endothelial cells
- Suppress the production and actions of humoral factors involved in the inflammatory process

Glucocorticoid Receptor Resistance

Several mechanisms may explain the clinical finding of GCR resistance, including alterations in the number, binding affinity, or phosphorylation status of GCR. Other possible explanations are polymorphic changes and/or overexpression of (co)chaperones, increased expression of inflammatory transcription factors, overexpression of the GCRβ isoform, the multidrug resistance pump, and altered membrane-bound (mGCR) expression.[11]

Nongenomic Actions of Glucocorticoids

Some regulatory effects of GCs occur within seconds or minutes. These are too rapid to result from genomic actions and must, therefore, be caused by nongenomic mechanisms of action. Three different rapid nongenomic actions of GCs have been described.[1,12,13]

cGCR-Mediated Nongenomic Actions

Dexamethasone can rapidly inhibit epidermal growth factor-stimulated cPLA2 (cytosolic PLA2) activation with subsequent arachidonic acid release.[12] This effect is thought to be mediated by occupation of cGCR, rather than changes in gene transcription, as the observed effect is RU486 sensitive (*i.e.,* GCR dependent) but actinomycin insensitive (*i.e.,* transcription independent). Chaperones or (co)chaperones of the multiprotein complex may act as signaling components to mediate this effect. Following GC binding, the cGCR is released from this complex to mediate classic genomic actions. However, there is also a rapid release of Src and other (co)chaperones of the multiprotein complex, which may cause rapid inhibition of arachidonic acid release. Similarly, dexamethasone has been reported to have cardiovascular protective effects, which are neither genomic (because they occurred too quickly and were actinomycin insensitive) nor nonspecific–nongenomic effects (because they occurred at a very low concentration [100 nM]).[13] These may involve binding of GCs to cGCRs, leading to nontranscriptional activation of phosphatidylinositol 3-kinase, protein kinase Akt, and endothelial NO synthase.

Nonspecific Nongenomic Actions

GCs are sometimes administered at very high doses. Systemic daily dosages >100 mg prednisone equivalent are regarded as "very high dose." "Pulse therapy" is the daily administration of ≥250 mg prednisone equivalent for 1 day or a few consecutive days[14] (see Table 86.1). At a daily dose of 100 mg prednisone equivalent, almost all cGCRs are completely saturated, which means that specificity (*i.e.,* the exclusivity of receptor-mediated effects) is lost. Nonspecific nongenomic actions occur in the form of physicochemical interactions with biological membranes, which probably contribute to the therapeutic effect.[1] Intercalation of GC molecules into cell membranes is thought to alter cell function by influencing cation transport and increasing mitochondrial proton leak. The resulting inhibition of calcium and sodium cycling across the plasma membrane of immune cells is thought to contribute to rapid immunosuppression and to reduced inflammation.

Such high GC doses are only used in a few clinical specialties, and this practice has been criticized by some endocrinologists and pharmacologists. Unfortunately, there are no randomized controlled trials of high-dose GC therapy, but it is often used with clinical success in acute exacerbations of life-threatening diseases and various clinical conditions resistant to other therapies. For example, pulsed intravenous (IV) methylprednisolone is effective in the treatment of systemic lupus erythematosus (SLE) and causes rapid immunosuppression in patients with organ- and/or life-threatening manifestations of SLE. However, the standard regime (1 g/day for 3 consecutive days) is associated with significant risks of infection, and lower doses may be just as effective.[15]

High-dose GCs are also often used in immune thrombocytopenia associated with SLE, although comparative studies are lacking.[16] It has been calculated that in such situations, the concentrations achieved *in vivo* are high enough (around 10–5 mol/L) to cause immediate nonspecific nongenomic effects on immune cells.[1] Intraarticular injections also bring high concentrations of GCs into contact with inflammatory cells, although it is difficult to assess locally achieved concentrations because crystal suspensions are most often used.

Specific Nongenomic Actions

GCs can also induce specific nongenomic actions, mediated through membrane-bound glucocorticoid receptors (mGCRs). The existence and function of membrane-bound receptors have been demonstrated for various steroids (including mineralocorticoids, gonadal hormones, vitamin D, and thyroid hormones).[1,17] Small numbers of mGCRs can be demonstrated by immunofluorescence on human peripheral blood mononuclear cells (PBMCs; monocytes and B cells) obtained from healthy controls.[17] The monoclonal antibody (mAb) used to detect mGCRs also recognizes cGCRs, suggesting that mGCRs are probably variants of cGCRs produced by differential splicing or promoter switching. Immunostimulation with lipopolysaccharide increases the percentage of mGCR$^+$ monocytes, and this can be prevented by inhibiting the secretory pathway with brefeldin A. This suggests that mGCRs are actively upregulated and transported through the cell after immunostimulation. These *in vitro* findings are consistent with observations that the frequency of mGCR$^+$ monocytes is increased in patients with rheumatic disorders and is positively correlated with disease activity in RA.[17] It remains unclear whether mGCRs are involved in pathogenesis. Alternatively, and perhaps more likely, they may cause negative feedback regulation.

GLUCOCORTICOID EFFECTS ON IMMUNE CELLS

Through the above mechanisms, GCs mediate a wide range of antiinflammatory and immunomodulatory effects, with virtually all primary and secondary immune cells affected to some extent (Table 86.2).[18]

KEY CONCEPTS

Definition of Conventional Terms for Glucocorticoid (GC) Dosages

Low dose	≤7.5 mg prednisone equivalent per day
Medium dose	>7.5 mg, but ≤30 mg prednisone equivalent per day
High dose	>30 mg, but ≤100 mg prednisone equivalent per day
Very high dose	> 100 mg prednisone equivalent per day
Pulse therapy	≥ 250 mg prednisone equivalent per day for 1 or a few days

TABLE 86.2 Important Effects of Glucocorticoids (GCs) on Primary and Secondary Immune Cells

Monocytes/Macrophages

↓ Number of circulating cells (↓ myelopoiesis, ↓ release)
↓ Expression of major histocompatibility complex (MHC) class II molecules and Fc receptors
↓ Synthesis of proinflammatory cytokines (*e.g.,* interleukin [IL]-2, IL-6, tumor necrosis factor [TNF]-α) and prostaglandins

T Cells

↓ Number of circulating cells (redistribution effects)
↓ Production and action of IL-2 (most important)

Granulocytes

↓ Number of eosinophil and basophil granulocytes
↑ Number of circulating neutrophils

Endothelial Cells

↓ Vessel permeability
↓ Expression of adhesion molecules
↓ Production of IL-1 and prostaglandins

Fibroblasts

↓ Proliferation
↓ Production of fibronectin and prostaglandins

(From Buttgereit F, Saag K, Cutolo M, et al. The molecular basis for the effectiveness, toxicity, and resistance to glucocorticoids: focus on the treatment of rheumatoid arthritis. Scand J Rheumatol 2005; 34: 14–21, with permission.)

The Role of Endogenous Glucocorticoids in Inflammatory Arthritis

Exogenous (therapeutic) and endogenous (physiological) GCs differ in several respects. The most important differences are in their relative mineralocorticoid and GC (antiinflammatory) activities. Exogenous and endogenous GCs also differ in their pharmacological characteristics, such as plasma kinetics, metabolism, biological half-life, lipophilicity, drug–receptor interactions, and nongenomic potencies.[19]

The actions of exogenous GCs as described above are well established. In contrast, we know relatively little about the role of endogenous GCs in arthritis. Although GC actions on target tissues are thought to be determined by GC plasma concentrations and the tissue-specific density of GCRs, it seems that endogenous GCs are subject to extensive prereceptor metabolism. Within target cells or tissues, GC action depends not only on plasma hormone levels, receptor expression, and receptor-effector coupling but also on local GC metabolism. Specifically, 11β-hydroxysteroid dehydrogenases appear to govern access of GCs to their cognate receptors by changing the balance between active and inactive GCs within the cell (reviewed in [19]). Thus the predominant reductase activity of 11β-hydroxysteroid dehydrogenase type 1 (11βHSD1) catalyzes the formation of bioactive cortisol from inactive cortisone (in humans) and corticosterone from 11-dehydrocorticosterone (in rodents). This nicotinamide adenine dinucleotide phosphate (NADPH)–dependent enzyme is present in many tissues and usually increases the intracellular availability of active GCs. In contrast, 11βHSD2 only possesses dehydrogenase activity: It inactivates active GCs and therefore decreases the intracellular concentration of bioactive GCs.

Proinflammatory cytokines, such as interleukin-1β (IL-1β) and tumor necrosis factor-α (TNF-α), stimulate 11βHSD1 and downregulate 11βHSD2 expression. Hence, specific proinflammatory cytokines can modulate local intracellular GC metabolism, which may affect their own proinflammatory effects. More recently, substantial GC metabolism has been shown in joints, since TNF-α and IL-1β induce 11βHSD1 activity in primary cultures of synovial fibroblasts isolated from synovial tissue biopsy specimens from patients with RA.[20]

In a rodent model of immune-mediated arthritis, targeted disruption of GC signaling in osteoblasts attenuates joint inflammation and cartilage destruction.[21] These results suggest that under the control of endogenous GCs, osteoblasts modulate immune-mediated inflammatory responses and, as a consequence, inflammation-induced cartilage damage and bone integrity. These findings are supported by evidence suggesting that the effects of GCs follow a dose–response curve, with permissive or even stimulatory effects at physiological concentrations and suppressive effects at pharmacological concentrations.[20]

THERAPEUTIC USE

A wide range of GC molecules are available for clinical use: The common basic structure has been modified to improve their usefulness in various clinical applications (Fig. 86.4). Despite their widespread use, the designation of GC treatment regimens is often imprecise. Recommendations for a standardized nomenclature for GC therapy are summarized below.[14]

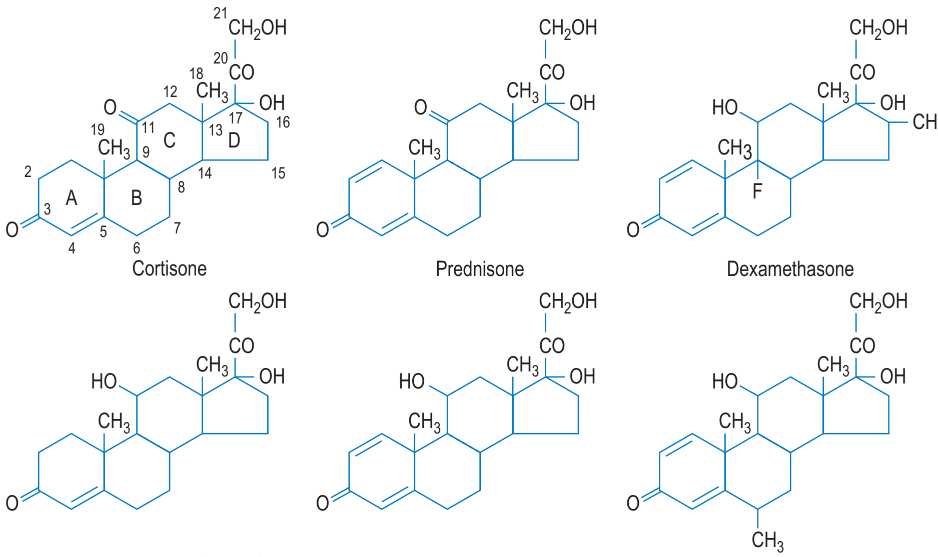
Terminology

Although the term *steroid* is widely used to describe this class of drugs, it is too broad, as it simply describes chemical compounds characterized by a common multiple-ring structure (including cholesterol, vitamin D, and sex hormones). Similarly, the terms *corticosteroid* or *corticoid* are not sufficiently precise, as the adrenal cortex synthesizes not only GCs but also mineralocorticoids and androgens. For these reasons, the terms *glucocorticoid* or *glucocorticosteroid* are preferred; however, *glucocorticoid* is the more widely used term.

When describing the use of GCs, it is necessary to define the drug, the dosage, the route of administration, and the timing, frequency, and duration of treatment.

Different GC drugs have different potencies, and they differ in their ability to produce the distinct therapeutic effects discussed above. Drug potencies are usually described by the equivalent dosages (relative potencies) to produce classic genomic effects (Table 86.3). These values have been used for decades, although the experimental and clinical evidence for their precise relative potency is weak. In practice, relative potencies are useful as a general therapeutic guideline in daily clinical practice, as long as they are not used dogmatically. It has, therefore, been suggested that we should continue to use relative potencies until more exact data are available and that doses of different GCs should be expressed in terms of "prednisone equivalent" (*i.e.,* doses of different GCs are expressed as equivalent to milligrams of prednisone [or prednisolone, as the potency of prednisone is equal to that of prednisolone]).

However, data indicate that the concept of equivalent dosages is only valid for doses less than 100 mg prednisone equivalent because nongenomic effects come into play at higher doses. The reason this is important is that the relative potencies of different GCs to produce these nongenomic effects are completely different



Cortisone

Prednisone

Dexamethasone

Hydrocortisone (cortisol)

Prednisolone

Methylprednisolone

FIG 86.4 Molecular Structures of Cortisone and Commonly Used Glucocorticoids (GCs). Carbon and ring nomenclature is indicated on cortisone molecule.

TABLE 86.3 Drug Potencies of Selected Glucocorticoids (GCs)

Cortisol	1 (per definition)
Prednyliden	3.5
Predniso(lo)ne	4.0
Methylprednisolone	5.0
Dexamethasone	25
Betamethasone	25

Drug potencies describe the potency of the respective drug to produce classical genomic (antiinflammatory) effects relative to cortisol. These potencies provide the basis for calculating equivalent dosages.

(Data from Lipworth BJ. Therapeutic implications of non-genomic glucocorticoid activity. Lancet 2000;356:87–9.)

from their classic genomic effects (see Table 86.3). For example, methylprednisolone is used for pulse therapy of exacerbations of immunologically mediated disorders. Prednisolone and methylprednisolone have similar genomic potencies, but when used for high-dose therapy, the nonspecific nongenomic effect of methylprednisolone is more than three times stronger. This may explain the apparent superiority of high-dose methylprednisolone. In contrast, betamethasone has very low nongenomic potency, which may be why this drug is considered less effective systemically, even though it has the same genomic potency as that of dexamethasone. In summary, the clinical usage of different GCs is clearly determined by the magnitude of their clinical efficacy, but another important factor in selecting which one to use is their nongenomic potency.

Glucocorticoid Treatment Regimens: General Aspects

For many decades, there has been confusion surrounding the terms used to describe dosage (very low, low, mild, mild to moderate, moderate, high, very high, ultrahigh, and mega) and by loose usage of such terms as “low-dose therapy,” “high-dose therapy,” and “pulse therapy.” A 2002 consensus statement has clarified this situation, partly to achieve scientific consistency and partly to recognize that GC actions are strongly dose dependent, both quantitatively and qualitatively. The standardized nomenclature for GC dosages and GC treatment regimens, as discussed below, is now recommended.[14]

Low Dose

Treatment with doses of up to 7.5 mg prednisone equivalent per day is considered low-dose GC therapy because these doses occupy less than 50% of the receptors. Such courses are frequently used for maintenance therapy and have relatively few adverse effects (*e.g.*, osteoporosis). As there may be relative hypocortisolism in chronic inflammatory conditions, such as RA and polymyalgia rheumatica, low-dose GCs act, in part, as replacement therapy for reduced adrenal GC production.

Medium Dose

GC doses of more than 7.5 mg but less than 30 mg prednisone equivalent per day are considered medium-dose therapy because they lead to a significantly higher receptor engagement between 50% and <100%. These doses are effective in modulating disease activity in various rheumatic diseases but may have considerable and dose-dependent adverse effects if given for longer periods.

High Dose

Treatment with doses of more than 30 mg and up to 100 mg of prednisone equivalent per day is considered high-dose therapy because these doses significantly increase receptor saturation, in a dose-dependent manner. At approximately 100 mg prednisone equivalent per day, receptor saturation is almost complete, and it is likely that genomic GC effects are fully exerted (see Table 86.1). High-dose therapy can be successfully given as initial treatment for subacute diseases, such as non-life-threatening exacerbations or visceral complications of RA or other connective tissue diseases, but cannot be administered over the long term because of the danger of severe adverse effects.

Very High Dose

Doses above 100 mg of prednisone equivalent per day are considered “very high.” At this level, there is virtually 100%

saturation of cytosolic receptors, so any further increase in dose may affect the pharmacodynamics (*e.g.,* receptor off-loading and reoccupancy), receptor synthesis and expression. At these doses, nongenomic effects may deliver additional therapeutic benefit, although it remains unclear whether these effects have any direct therapeutic relevance. Experimental data suggest that these differential effects come increasingly into play above ≈100 mg/day (see Table 86.1). Doses of >100 mg of prednisone equivalent per day are frequently (and successfully) given as initial treatment for acute or life-threatening exacerbations of connective tissue diseases, vasculitis, and RA. These doses cannot be administered over the long term because of their severe adverse effects.

Pulse Therapy

Pulse therapy involves administration of ≥250 mg prednisone equivalent per day (usually intravenously) for a short period (typically 1–5 days, rarely longer). At such high doses, the nongenomic potencies of GCs come into play. It is likely that these explain the success of very high doses and pulse therapy in acute exacerbations of immunologically mediated diseases. The immediate effects of very high doses may be additive to the genomic effects mediated by cGCRs. These additional effects may make a crucial contribution to the therapeutic effect by terminating acute exacerbations. Circumstances where very high doses or pulse therapy can be successful include acute episodes or particularly severe forms of rheumatic diseases, such as SLE, vasculitis, polymyositis, and RA (see below).

Alternate-Day Regimens

Alternate-day regimens were introduced for long-term oral GC therapy with the aim of minimizing undesirable adverse effects, such as suppression of the hypothalamo–pituitary–adrenal (HPA) axis. Instead of daily dosing, a single dose is administered every other morning, usually in a dose equivalent to or somewhat higher than twice the usual daily dose. The idea behind this regimen is to allow the HPA axis to remain active by exposing the body to exogenous GC on alternate days instead of suppressing it every day. This strategy only works if the HPA axis is still active, and, unfortunately, patients often experience breakthrough symptoms on the second day of treatment. Alternate-day regimens are used rarely these days except in patients with juvenile idiopathic arthritis, in whom alternate-day GC regimens cause less inhibition of body growth.

Glucocorticoid Withdrawal Regimens

Because of their significant adverse effects, GCs are usually reduced or stopped as soon as the disease is under control. This needs to be done carefully to avoid a relapse in disease activity and to permit recovery of adrenal function. There are no controlled comparative studies to support a specific regimen for weaning patients off GCs, as this process needs to be adjusted according to disease activity, dose/duration of therapy, and clinical response. When patients with RA are treated with up to 10 mg/day of prednisone, the daily dose can be reduced by 2.5 mg every month until 5 mg/day is reached. Thereafter, doses can often be reduced by 1 mg per month. When higher doses have been used, a reduction by 5 mg every 1–2 weeks down to 20 mg/day is often well tolerated, followed by further reductions of 1–2.5 mg/day every 2–3 weeks. Addition of immunomodulatory drugs, such as methotrexate and azathioprine, may allow further dose reductions. Short courses of GCs for some conditions, such as asthma, may be ceased without tapering if the total treatment course is less than 14 days in duration. With longer periods of treatment, the dose should be reduced gradually to allow the HPA axis to recover, but the rate of reduction is usually faster than for rheumatological conditions.

Glucocorticoids in Rheumatoid Arthritis: an Example

GCs are crucially important in the management of RA and are used in various dosages at different disease stages. RA is, therefore, a useful example to discuss GC therapy in more detail.

Low-Dose Maintenance Therapy

In early RA, GC in doses <10 mg are highly effective for relieving symptoms in patients with active arthritis. Many patients are functionally dependent on this low-dose therapy and continue it over the long term.[22] Improvement has been documented not only in all clinical parameters, including pain scales, joint scores, morning stiffness, and fatigue, but also in acute inflammatory markers, such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). After 6 months of therapy, the beneficial effects of GCs seem to diminish, but if therapy is then tapered and stopped, patients often experience an exacerbation of symptoms within a few months.

The disease-modifying properties of GCs were first described in 1995, in a 2-year trial of 7.5 mg prednisolone in patients who had RA of short or intermediate disease duration and were treated with NSAIDs (95%) and disease-modifying antirheumatic drugs (DMARDs) (71%).[23] Nowadays, GCs are considered to have disease-modifying properties in early RA, but it is less clear whether they inhibit the progression of erosions in RA of longer duration. A meta-analysis of 15 studies that included 1414 patients concluded that GCs given in addition to standard therapy can substantially reduce the rate of erosion progression in RA.[24] Another meta-analysis of 70 randomized placebo- or drug-controlled studies found similar effects of DMARDs, GCs, and biologicals on radiographic progression in RA.[25]

Glucocorticoid Pulse Therapy

GC pulse therapy is used to treat some serious complications of RA and to induce remission in active disease, for example, when initiating second-line antirheumatic treatment. Pulse therapy with methylprednisolone 1 g/day, dexamethasone 200 mg/day, or equivalent, given intravenously for 1–3 days, was shown to be effective in most studies, demonstrating a beneficial effect that generally lasted for about 6 weeks, albeit with large variations. This means that it is not wise to apply pulse therapy in active RA, unless the therapeutic strategy is changed (*e.g.,* DMARD treatment introduced to maintain the remission induced by pulse therapy).

Intraarticular Glucocorticoid Injections

Intraarticular injections with GCs are often used in RA. The benefit achieved varies, depending on several factors, such as the joint treated (size, weight-bearing or non–weight-bearing), inflammatory activity, the volume of synovial fluid in the joint, whether or not synovial fluid was aspirated before the injection, the choice and dose of GC preparation, injection technique, and whether the joint is rested after the injection.[26] To prevent GC-induced joint damage, it is recommended that intraarticular GC injections should not be repeated more often than once every 3–4 weeks, and no more than 3–4 times a year in a weight-bearing joint.

KEY CONCEPTS

Glucocorticoid (GC) Therapy in Rheumatoid Arthritis (RA)

Our view of the risk–benefit ratio of low-dose GC has shifted in recent years:

- GCs can now be considered as disease-modifying antirheumatic drugs, especially in early RA.
- Adverse effects of low-dose GCs are less abundant and less severe than previously suggested, and some (*e.g.*, osteoporosis) can be well managed.
- The goal of antirheumatic treatment in early RA is to induce remission of disease by aggressive management: GCs are part of this aggressive strategy.

Adverse Effects

Studies of GC toxicity tend to be retrospective and observational. This can make it difficult to differentiate unfavorable outcomes attributable to GCs from those occurring as a result of the underlying disease or other comorbidities. Furthermore, there is a strong selection bias for GC use, as physicians are more inclined to use them in patients with more severe disease. Frequent, but less serious, adverse effects (*e.g.*, skin thinning, Cushingoid appearance) may be of great concern to patients, whereas more debilitating toxicities, such as osteoporosis, cataracts, and GC-induced hypertension, may initially go unrecognized or be asymptomatic. Interpretation of toxicity data is further confounded by the use of GCs at variable points in the disease course, limited data defining "threshold" doses for particular adverse events, and the fact that toxicity reports cover a heterogeneous group of GC-treated diseases.

Compared with other antirheumatic agents, GCs have a low incidence of short-term symptomatic toxicity, and patients rarely discontinue therapy for this reason. Despite >60 years of use, we still lack robust data on the longer-term toxicities of GCs from large randomized controlled trials with long-term follow-up. The most common GC toxicities are summarized below.

Some progress has been made by formulating recommendations on which adverse effects of GC treatment should be monitored in RA, how to monitor them, and how often. Two levels of monitoring GC adverse events have been proposed: *(i)* for routine clinical practice, details are given on how to identify adverse events in a systematic and practical way, and this should result in preventive and therapeutic measures to minimize the risks of GC therapy; and *(ii)* for clinical trials, recommendations have been made on how to accurately assess the frequency and severity of a wider range of adverse events.[27]

Osteoporosis

Glucocorticoid-induced osteoporosis (GIOP) is the most important potential complication of prolonged GC therapy. Chronic GC treatment results in rapid and profound reductions in bone mineral density, with most bone loss occurring during the first 6–12 months of treatment.[2,28]

GIOP initially affects trabecular bone, but cortical bone is also affected with more chronic use, at such sites as the femoral neck. Precisely how GCs affect bone remains obscure. GCs decrease calcium absorption, increase renal calcium loss, diminish sex and growth hormone production, induce muscle wasting, and modulate RANKL/OPG, NF-κB, and AP-1 signaling in bone.[2] All of these changes lead to enhanced osteoclast function and lifespan and thus to increased bone resorption. Consequently, markers of bone resorption are often increased in patients treated with GCs.[2] However, reduced bone formation as a result of reduced osteoblast function is likely to be a more important effect of GCs on skeletal health. Oral doses of prednisone as low as 2.5 mg/day have been shown to suppress serum osteocalcin, a marker of bone formation. Histologically, mean wall thickness is reduced, reflecting the reduced amount of bone replaced in each remodeling unit. *In vitro,* osteoblasts and their precursors are highly GC responsive. Here, the predominant effect is to promote osteoprogenitor proliferation, lineage commitment, and osteoblast differentiation, resulting in the formation of bone nodules of increased size and numbers. However, GCs also inhibit type I collagen expression and reduce preosteoblastic replication. Finally, GCs promote apoptosis of osteoblasts and osteocytes. The inhibitory effects of GCs on bone formation may partly be a result of downregulation of insulin-like growth factor 1 (IGF-1) expression by osteoblasts. Fortunately, we now have effective strategies for the prevention and treatment of GC-induced osteoporosis, using calcium, vitamin D, and specific osteotropic agents, such as bisphosphonates or parathyroid hormone.[28]

Osteonecrosis

Osteonecrosis has long been considered an important consequence of high-dose GC use. In a Japanese study of femoral head osteonecrosis, 35% of cases were related to GC treatment. Higher average dose may be a more important predictor of avascular necrosis of bone compared with cumulative dose. Osteonecrosis is particularly noted in SLE but rarely occurs in patients with RA receiving low-dose therapy, affecting <3% of patients. Osteonecrosis rarely occurs in patients with SLE on prednisone doses <20 mg/day.

Myopathy

As with osteonecrosis, GC-induced myopathy is rare in patients receiving low-dose GCs. In small studies, myopathy appears more closely associated with fluorinated GC preparations, such as triamcinolone, than with prednisone. Notably, myopathy has been reported after only 3 months' treatment with triamcinolone 8 mg/day. In general, myopathy attributable to prednisone only occurs after higher doses and longer durations of treatment.

Cardiovascular Adverse Effects

GC-induced hypertension seems to be, at least in part, mediated via fluid retention (as a result of mineralocorticoid effects); it is dose related and less likely with medium-dose or low-dose therapy. Individual variation in susceptibility and other factors, such as the starting level of blood pressure, dietary salt intake, functional renal mass, associated diseases, and drug therapy, may also play a role.

Another troublesome potential toxicity of low-dose GC is the development of premature atherosclerotic vascular disease. This has proven difficult to investigate: studies evaluating the effects of GCs on lipids and atherosclerosis in patients with RA have yielded mixed results, with some studies suggesting that GCs may, in fact, reverse unfavorable lipid changes. At present, there is no evidence of a strong association between low-dose

GCs and cardiovascular disease in RA, even though atherosclerotic vascular disease is known to be accelerated in patients with Cushing syndrome. Systemic GC use during pregnancy may also have epigenetic effects leading to adult hypertension in the next generation.[29]

Dermatological Adverse Effects

Skin thinning and ecchymoses are common adverse events with GCs, even at low doses. Cutaneous atrophy results from the catabolic effects of GCs on keratinocytes and fibroblasts. Purpura and easy bruising in GC-treated patients probably result from decreased vascular structural integrity. A Cushingoid appearance is very troubling to patients but is uncommon at doses below the physiological range. One study reported facial fullness ("moon facies") in 13% of patients receiving 4–12 mg triamcinolone for up to 60 days. These adverse effects are observed in over 5% of patients exposed to ≥5 mg prednisone equivalent for ≥1 year. The incidence of iatrogenic Cushing syndrome is dose dependent and generally becomes evident after >1 month of GC therapy.[30] Alternate-day therapy may reduce the incidence, although there are only limited data supporting this concept. GC-induced acne, hirsutism, and striae are other undesirable dermatological effects that occur even with lower doses.

Gastrointestinal Adverse Effects

GCs are considerably less toxic to the upper gastrointestinal (GI) tract compared with NSAIDs. If GCs independently increase the risk of GI events (*e.g.,* gastritis, ulceration, bleeding), the effect is slight, with estimated relative risks varying from 1.1 (not significant) to 1.5 (marginally significant). There have also been anecdotal reports of intestinal rupture, diverticular perforation, and pancreatitis attributed to low-dose GC therapy. GCs are frequently used concurrently with NSAIDs in RA, and meta-analyses have confirmed that the combination of the two drugs synergistically increases the risk of adverse GI events. In a large-scale study based on the UK General Practice Research Database, the risk of upper GI complications was 1.8 (95% confidence interval [CI] 1.3–2.4) times higher in GC users than in nonusers. The risk tended to be greater with higher GC doses, but the dose gradient was not statistically significant. The risk was >12 times higher in those taking both GCs and NSAIDs than in those not using either. No studies have yet looked at the GI effects of combining GCs with cyclooxygenase 2 (COX-2)–selective NSAIDs. Preventive strategies for the adverse effects of GC on the GI tract have been reviewed by Caplan et al.[30]

Infectious Diseases

Medium- to high-dose GC therapy may increase the risk of serious infections leading to hospitalization or surgery, particularly when administered for prolonged periods. However, there is no evidence that infection rates are increased in patients on doses of prednisone below 10 mg/day or cumulative doses below 700 mg. In those taking higher doses, the risk of infection appears to be lessened with alternate-day therapy.

In GC-treated patients, physicians should be aware of the risk of infections with typical and atypical organisms, recognizing that GCs may blunt classic clinical features and delay diagnosis. However, it is difficult to separate the independent effects of GC use from those of other commonly used antirheumatic agents, such as methotrexate and anti-TNF-α agents.[31] At present, the independent role of GCs in facilitating herpes zoster virus (HZV) infection in patients with RA remains uncertain.

Other Adverse Effects

Adverse effects on the HPA axis and on glucose metabolism are reviewed elsewhere, together with neuropsychiatric and ophthalmological adverse effects.[30,32,33]

IMPORTANCE OF TIMING OF GLUCOCORTICOID ADMINISTRATION

In patients with RA, major symptoms, such as pain, inflammation, and stiffness, vary during the course of the day, usually with the highest severity in the morning hours. These symptoms are preceded by elevated levels of proinflammatory cytokines. On the basis of these considerations, it has been proposed that altering the timing of GC administration may help optimize RA therapy.[19,34]

NEW GLUCOCORTICOID RECEPTOR LIGANDS ON THE HORIZON

The various mechanisms of GC action provide interesting opportunities for developing optimized GCs and GCR ligands.

Selective Glucocorticoid Receptor Agonists

The genomic component mechanisms of transactivation and transrepression offer the opportunity to develop GCR ligands that predominantly cause transrepression rather than transactivation. This concept is based on the proposition that the antiinflammatory properties of GCs mostly result from repression of AP-1–stimulated and NF-κB–stimulated synthesis of inflammatory mediators, whereas their adverse effects are associated with transactivation of genes involved in metabolic processes. Investigators have, therefore, sought novel GCR ligands with high transrepression activity but low effect on transactivation. One such compound, A276575, exhibits a high affinity for the GCR and potently represses IL-1α–induced IL-6 production, similar to dexamethasone. However, unlike dexamethasone, A276575 induces little aromatase activity. Other novel nonsteroidal GCR ligands that possess high repression activities against inflammatory mediator production but have lower transactivation activities than traditional GC are being developed. Substances that cause a receptor conformation preferring a GCR–protein interaction as opposed to a GCR/DNA binding–dependent mechanism are called *selective glucocorticoid receptor agonists* (SEGRA) or "dissociated glucocorticoids." The SEGRA concept has, however, been challenged by studies on a mouse knock-in strain with a dimerization-deficient GCR, which demonstrated that some inflammatory processes can be suppressed by GCs and others cannot.[35] Also, these mice exhibited the classic adverse effects of GCs, such as GC-induced osteoporosis. Thus depending on the process being treated, SEGRA could be therapeutically more effective or less effective; moreover, not all adverse effects of GC therapy may be reduced.[35,36] As of now, whether SEGRA will become clinically relevant in practice remains uncertain.

Nitrosteroids

Nitrosteroids are another new class of GC drugs that have been tested in RA and inflammatory bowel disease (IBD). In addition to their enhanced GC properties, nitrosteroids release low levels of NO and have fewer undesirable effects. The prototype of these new steroids, 21-NO-prednisolone (NCX-1015), is much more potent than prednisolone in models of acute and chronic inflammation, including experimental arthritis induced by collagen II.

In contrast, NCX-1015 did not activate primary osteoclast activity *in vitro,* whereas prednisolone did. This lack of adverse effect of NCX-1015 seems to be chiefly caused by NO. It has been suggested that posttranslational modification of GCR (tyrosine nitration) by NCX-1015 may explain its enhanced antiinflammatory activity. Moreover, NCX-1015 potently stimulates IL-10 production, suggesting that nitrosteroids induce Tregs that negatively modulate inflammation. However, further work is needed to confirm the utility of nitrosteroids in clinical practice.

Long-Circulating Liposomal Glucocorticoids

The antiinflammatory efficacy of GCs can be improved by the additional benefits of nongenomic actions at high GC concentrations. This has led to the use of long-circulating liposomal GCs in experimental models. In rats with experimental autoimmune encephalitis, GC-containing liposomes accumulated at sites of inflammation, reaching concentrations >10–5 mol/L for ≥18 hours. These liposomes may be therapeutically superior to conventional intravenous high-dose GC therapy, as evidenced by their successful use in rats with adjuvant-induced arthritis. A single injection of 10 mg/kg liposomal prednisolone phosphate resulted in complete remission of the inflammatory response for almost a week. In contrast, the same dose of unencapsulated prednisolone phosphate did not reduce inflammation and had only a slight effect after repeated daily injections. It may be that preferential delivery of GCs to the site of inflammation leads to very high GC concentrations at the inflamed joint, but lower plasma concentrations with a consequent lower rate of adverse effects. These are very promising developments that exploit the broad spectrum of therapeutically relevant genomic and nongenomic GC actions at the site of inflammation.

Combining Prednisolone and Dipyridamole

Another interesting recent development is the selective amplification of GC antiinflammatory activity through synergistic multitarget action with another drug.[18] The combination of prednisolone and the antithrombotic drug dipyridamole synergistically suppresses the release of proinflammatory cytokines and produces antiinflammatory activity in acute and chronic disease models (including arthritis) at a subtherapeutic dose of prednisolone. This approach may create a dissociated activity profile with an increased therapeutic window through cellular network selective amplification of GC-mediated antiinflammatory signalling.[18] However, the exact molecular mechanism underlying the observed synergy and multitarget action of these two drugs remains obscure.

CONCLUSIONS

GCs are extremely valuable antiinflammatory agents with a range of actions that are useful in the management of inflammatory conditions, including arthritis and asthma. Combination therapy with biological agents may achieve superior benefit in rheumatological disease compared with either class of treatment alone,[37] but GCs will remain important drugs for many years to come. Recent research on GCs has highlighted the effects of cytosolic GCRs on intracellular signaling, transcription processes, and gene expression. Exploration of membrane-bound GCRs, dose–effect relationships, and the timing of GC administration have stimulated intensive research activity aimed at improving the efficacy–risk ratio. Modified-release prednisone has been already approved for the treatment of RA and the associated morning stiffness.[38] Further clinical developments seem likely to follow (*e.g.,* new GCR ligands and liposome encapsulation), all with a view to improving the risk–benefit ratio of GC therapy and the well-being of patients.

ON THE HORIZON

- Selective activators of transrepression (SEGRA)
- Nitrosteroids (with effect of nitric oxide on endothelium)
- Modified release steroids
- Liposomal encapsulation
- Optimized combinations with biologicals

MULTIPLE-CHOICE QUESTIONS

1. Genomic effects of glucocorticoids (GCs) include ALL of the following except:
   - **A.** Induction of antiinflammatory cytokines
   - **B.** Inhibition of arachidonic acid release
   - **C.** Interaction with transcription factors AP-1 and nuclear factor-κB
   - **D.** Competition for nuclear coactivators

2. The most important complication of GC use is:
   - **A.** Increased risk of infections
   - **B.** Diabetes mellitus
   - **C.** Osteoporosis
   - **D.** Glaucoma

3. Promising future prospects for steroid development include:
   - **A.** Liposomal encapsulation
   - **b.** Nitrogenated steroids
   - **C.** Slow release preparations
   - **D.** Selective inducers of transactivation

87

Immunomodulating Pharmaceuticals

Gideon P. Smith, Edwin S.L. Chan

Excitement over biologic agents and their capacity to regulate immunological reactions that significantly impact on such immunologically mediated diseases, such as rheumatoid arthritis (RA) and inflammatory bowel disease (IBD), has overshadowed the older, small-molecule therapeutic agents. Nonetheless, when tested head-to-head, some small-molecule agents (most notably methotrexate) have proven to be almost as effective as biologics; moreover, combining small-molecule therapies with biological agents generally leads to significantly better outcomes than use of either agent alone.[1] Thus it is likely that small-molecule immunomodulatory drugs will continue to be in wide use. Here, we review the most widely accepted and commonly used immunomodulators currently in clinical use.

METHOTREXATE

Methotrexate (Fig. 87.1) was employed in the treatment of RA as early as 1951, but its popularity with regard to RA did not come until the 1980s. Over the years, extensive experience with its use in inflammatory diseases as diverse as RA (Chapter 52), psoriasis (Chapter 64), and IBD (Chapter 75) has taught us a great deal about its safety, efficacy, and toxicity, as well as its antiinflammatory mechanisms of action. In this respect, methotrexate, much as corticosteroids, can be justly regarded as a cornerstone of immunomodulatory therapy.

Pharmacokinetics of Methotrexate

As an antiinflammatory agent, methotrexate is administered at low doses (usually 10–25 mg/week) once weekly, usually orally, but it can also be given subcutaneously or intramuscularly. At these doses, oral bioavailability is high (60–70%), and although transporters are responsible for its absorption from the gastrointestinal (GI) tract, saturation effect does not occur. A small portion of methotrexate is metabolized by hydroxylation into 7-hydroxymethotrexate. Both compounds have a serum half-life of no more than 8 hours. The much longer antiinflammatory action, which allows for once-weekly dosing, must therefore be mediated by other longer-lasting metabolites, such as polyglutamates. Excretion occurs principally via the urinary tract but also via the biliary tract. Therefore renal function is an important consideration in methotrexate dosing, and any medication that impairs glomerular filtration may also potentiate methotrexate's effectiveness and toxicity.[2]

Mechanisms of Action for Methotrexate

As an analogue of folic acid, methotrexate is an inhibitor of purine and pyrimidine synthesis and thereby suppresses cellular proliferation (Table 87.1). These actions are dependent on inhibition of dihydrofolate reductase; hence toxicities arising from high-dose methotrexate therapy can be treated with folic acid derivatives, such as leucovorin. However, folic or folinic acid, which are often given in conjunction with methotrexate in inflammatory diseases to reduce the incidence of mucositis and bone marrow suppression, do little to inhibit its antiinflammatory efficacy. Decreases in purine and pyrimidine concentrations in the serum have been observed following a single dose of methotrexate, along with decreased proliferation of antigen-stimulated lymphocytes. However, these changes are transient and insufficient to explain the antiinflammatory effectiveness of once-weekly dosing. This, as well as the low doses of methotrexate required to produce an antiinflammatory effect, suggests that the antiinflammatory actions are mediated via different mechanisms.

Methotrexate also blocks intracellular transmethylation reactions and inhibits production of *S*-adenosylmethionine. Since *S*-adenosylmethionine is necessary for formation of the toxic polyamine metabolites spermine and spermidine, their accumulation at the inflammatory site is prevented. This inhibition of transmethylation is associated with an impairment of monocyte and lymphocyte function and thus potentially the synthesis of reactive oxygen species. However, diminution of transmethylation by the use of the *S*-adenosylhomocysteine hydrolase inhibitor, deaza-adenosine, has failed to produce any beneficial clinical effects in RA.

Methotrexate and its long-acting polyglutamate metabolites also exert antiinflammatory effects by releasing the endogenous autocoid adenosine.[3] As potent inhibitors of the enzyme 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase, methotrexate polyglutamates promote accumulation of AICAR in tissues. Since AICAR inhibits catabolizing enzymes for both adenosine and adenosine monophosphate (AMP), which can be dephosphorylated to adenosine, the net effect is intracellular and extracellular increases in adenosine levels. These metabolic pathways are pharmacologically relevant, since aminoimidazole carboxamide and adenosine have been shown to be increased in urine following low-dose methotrexate treatment in patients with psoriasis.[4] Adenosine causes diminution of neutrophil accumulation, adhesion, phagocytosis and generation of reactive oxygen species, inhibition of adhesion molecule expression, suppression of proinflammatory cytokines, and induction of antiinflammatory cytokines, as well as modulation of macrophage and endothelial function.[2] Indeed, blockade of adenosine receptors reversed the antiinflammatory effects of methotrexate on animal models. It has also been suggested that

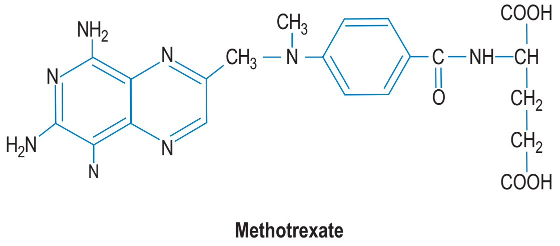

FIG 87.1 Methotrexate—chemical structure.

TABLE 87.1 Methotrexate: Mechanisms of Action

Suggested Mechanism	Rationale
Folate antagonism	Prevents purine and pyrimidine synthesis required for the proliferation of actively dividing immune cells, such as lymphocytes
Inhibition of spermine and spermidine production	Reduces formation of polyamines harmful to tissues
Alteration of cellular redox state	Reversible inhibition of lymphocyte and macrophage functions
Release of adenosine	Generation of a potent endogenous antiinflammatory mediator through inhibition of catabolism of both adenosine and adenosine monophosphate

caffeine, itself a nonselective antagonist of adenosine receptors, may both reduce the effectiveness of methotrexate in RA and protect against the development of cirrhosis of the liver, a major side effect of methotrexate.[5]

Adverse Effects

THERAPEUTIC PEARLS

Methotrexate

Proven safety profile
Concomitant administration of folic acid advisable
Antiinflammatory effects may be reduced by heavy use of caffeine
Hepatotoxicity a rare but real concern
Risk of hepatotoxicity increased with:
- Alcohol use
- Hepatitis
- Diabetes
- Obesity
- Alpha-1-antitrypsin deficiency

Over the years, methotrexate has proven to be one of the safest disease-modifying antirheumatic drugs (DMARDs) in use. Serious side effects such as cirrhosis are much less common than previously thought (Table 87.2). The use of folic acid has decreased the occurrence of mucosal and GI side effects, without limiting its antiinflammatory activity, and cytopenias are managed adequately with regular blood counts. Although side effects, such as nausea and vomiting, may resolve spontaneously or respond to dose reduction or folic acid supplementation, mild transaminasemia has rarely led to discontinuation of the medication. Risk of serious hepatotoxicity over 5 years of use is likely to be less than 1 in every 1000 patients with RA but may be more common among those with psoriasis. Risk factors, such as ethanol consumption, hepatitis B and C, diabetes, obesity, and alpha-1-antitrypsin deficiency, identify patients most likely to develop methotrexate-induced hepatic injury. However, other serious side effects, such as pneumonitis, may be overlooked, since early symptoms (mild cough or shortness of breath) are often ignored. Early identification allows for prompt discontinuation. The risk of developing solid tumors is debated, since the risk of malignancies is intrinsic to some of the conditions, such as RA, for which methotrexate is used. It is likely the risk of drug-induced malignancy is real, since reports have documented tumor regression following discontinuation of methotrexate, but the risk remains extremely small.

Impotence
Headache
Opportunistic infections

SULFASALAZINE

Sulfasalazine (Fig. 87.2) was originally introduced in the late 1930s for the treatment of RA but is now used in a wide range of inflammatory diseases, in particular, IBD and the seronegative arthritides. It consists of a derivative of the antiinflammatory salicylic acid, 5-amino-salicylic acid, and the antimicrobial sulfapyridine. These two moieties are joined together by an azo bond. Which component is responsible for the drug's antiinflammatory actions is unclear, but it appears to vary according to disease states. For instance, in IBD, 5-amino-salicylic acid is likely the main active component, as it is poorly absorbed following metabolism by intestinal flora. In inflammatory arthritides, sulfapyridine is likely to play a more important role, as it is relatively well absorbed and has a bioavailability in the region of 60%. Since acetylation is the principal route of metabolism of sulfapyridine following absorption, acetylator status is a major determinant of the plasma half-life. For the same reason, slow acetylators are more liable to develop side effects.

Mechanisms of Action for Sulfasalazine

KEY CONCEPT

Sulfasalazine: Mechanism of Action

Suppresses the proliferation of lymphocytes
Suppresses proinflammatory cytokine production
Inhibits activation of nuclear factor (NF)-κB
Promotes adenosine accumulation

Sulfasalazine has a number of immunomodulatory effects. Lymphocyte proliferation is suppressed *in vitro* and involves both B-cell and T-cell populations. *In vivo,* a decrease in activated lymphocytes in the peripheral blood is also seen. Tumor necrosis factor-α (TNF-α) production is suppressed, and receptor binding is inhibited. Sulfasalazine also inhibits activation of the transcription factor, nuclear factor (NF)-κB. Like methotrexate, sulfasalazine inhibits AICAR transformylase and thus promotes accumulation of adenosine and its antiinflammatory actions via the adenosine A_{2A} receptor. Indeed, treatment of animals with an adenosine A_{2A} receptor antagonist reversed sulfasalazine's reduction of leukocyte accumulation in an air-pouch model of inflammation.

Adverse Effects

In a large series, a quarter of those treated over 11 years stopped treatment because of toxicity.[6] Most toxicities occurred early and were both trivial and resolved following therapy withdrawal. Most common are nausea, vomiting, anorexia, and rash. Serious cutaneous reactions, such as exfoliative dermatitis or Stevens-Johnson syndrome, are rare. Transaminasemia and drug-induced hepatitis can occur. Blood dyscrasias with megaloblastic anemia, neutropenia, aplastic anemia, and myelodysplastic syndrome may arise. Neurological adverse effects include headache and dizziness or, more seriously, peripheral neuropathy, Guillain-Barré syndrome, or transverse myelitis. Sulfasalazine should be avoided in patients with sulfa allergy, and glucose-6-phosphate dehydrogenase (G6PD) deficiency screening should be performed before prescribing.

AZATHIOPRINE

Azathioprine, an imidazolyl derivative of 6-mercaptopurine (Fig. 87.3), has been widely used in RA and IBD as well as in solid organ transplantations. Cleavage into 6-mercaptopurine and the imidazole moiety occurs rapidly within erythrocytes, both enzymatically by glutathione transferase and nonenzymatically. Several enzymes (Table 87.3) participate in the metabolism of 6-mercaptopurine into active and inactive compounds. One of these, thiopurine methyltransferase, is associated with genetic polymorphisms; inherited changes in its activity may impact patient response to azathioprine. Xanthine oxidase inactivates 6-mercaptopurine by converting it to 6-thiouric acid. Since this occurs mainly in the liver, toxicity from azathioprine therapy is a danger in enzyme deficiency states, as a result of disease or use of drugs, such as allopurinol.

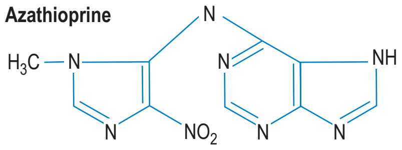

FIG 87.3 Azathioprine—chemical structure.

Proposed Mechanisms of Action for Azathioprine

The immunomodulatory mechanism of azathioprine remains unclear. As purine analogues, the active metabolites interfere with the salvage pathway and *de novo* synthesis of purines, and they are incorporated into RNA and DNA. Proliferation of T and B lymphocytes is inhibited, and function of natural killer (NK) cells is suppressed without any change in cell numbers. The production of antibodies is also suppressed, although it is not known which of these effects predominate *in vivo.* Cellular responses to chemoattractants are altered, and the production of cytokines, such as interleukin-6 (IL-6), is also affected.

Adverse Effects

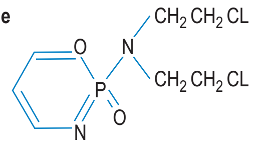
Azathioprine is generally well tolerated. The most common side effects are mild and affect the GI system. Pancreatitis can occur as an idiosyncratic reaction. Hepatotoxicity and cholestasis are not uncommon, and hepatic peliosis and nodular regenerative hyperplasia occur rarely. There have been reports of a possible heightened risk for non-Hodgkin lymphoma, but because of the rarity of these events, no definite link has been established between azathioprine and malignancies. Bone marrow suppression and opportunistic infections pose far greater threats.

CYCLOPHOSPHAMIDE

Alkylating agents were used in the treatment of inflammatory diseases after promising reports on using nitrogen mustard in RA. Cyclophosphamide (Fig. 87.4) is metabolized to produce the alkylating agent phosphoramide mustard as well as acrolein, which, although inactive, results in the hemorrhagic cystitis associated with cyclophosphamide. Cyclophosphamide can be given intravenously, but bioavailability following oral administration is high (>75%). Toxicity has severely limited its use in inflammatory diseases, although its contribution to the management of lupus nephritis cannot be denied. The alkylating actions occur at guanine residues (principally on DNA but also on RNA) resulting in cross-linkable strands and disruption of transcription and translation.

TABLE 87.3 Principal Enzymes Involved in the Metabolism of Azathioprine

Enzyme	Action
Glutathione transferase	Cleaves azathioprine into 6-mercaptopurine and imidazole moieties
Thiopurine methyltransferase	Metabolism of 6-mercaptopurine
Xanthine oxidase	Conversion of 6-mercaptopurine to 6-thiouric acid



Cyclophosphamide

FIG 87.4 Cyclophosphamide—chemical structure.

Mechanisms of Action of Cyclophosphamide

This alkylating process has immunomodulating effects on resting and actively dividing cells. The numbers of circulating CD4 T lymphocytes and, to a lesser extent, CD8 T lymphocytes are reduced, thus reducing the CD4/CD8 ratio. Despite an apparent increase in immunoglobulin-secreting cells, B-cell function is suppressed, and overall immunoglobulin synthesis is reduced.

Adverse Effects

The best known toxicity is hemorrhagic cystitis. Since this occurs more frequently following oral dosing, this route of administration is rarely used. This may relate to continuous exposure of the bladder to acrolein, so the acrolein-neutralizing agent 2-mercaptoethane sulfonate (Mesna) is used prophylactically along with copious hydration. Hemorrhagic myocarditis can also occur and may cause myocardial necrosis, hemopericardium, and congestive cardiac failure. However, survivors of acute cardiac toxicity do not show any residual electrocardiographic or echocardiographic abnormalities.

Besides bone marrow suppression, reduction of fertility, and a heightened risk of infection, cyclophosphamide therapy has been associated with secondary malignancies, which may occur years after drug cessation. Malignancies of the bladder, often of a transitional cell type, tend to occur only in those with a history of treatment-related hemorrhagic cystitis. Myeloproliferative and lymphoproliferative disorders have also been associated with cyclophosphamide use.

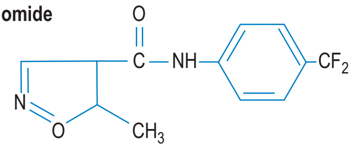
Other Nitrogen Mustard Derivatives

Chlorambucil, or 4-[bis(2chlor-ethyl)amino]benzenebutanoic acid, has wide distribution in tissue and 87% oral bioavailability, but unlike cyclophosphamide, it does not require metabolism by the liver to become metabolically active.[7] The only indication approved by the US Food and Drug Administration (FDA) is for treatment of chronic lymphocytic leukemia (CLL), but like cyclophosphamide, chlorambucil has been reported to be used in treatments for the same wide range of inflammatory conditions. The mechanism of action and side effect profile is also similar to those of cyclophosphamide, but with a higher risk of permanent aplasia.[8]

Melphalan is another phenylalanine derivative of nitrogen mustard, mainly used in treating multiple myeloma. It has been less widely adopted but has been used off-label in a variety of inflammatory conditions. Adverse effects and mechanism are the same as those of cyclophosphamide, as described above.

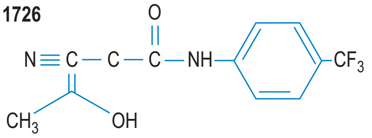
LEFLUNOMIDE

Leflunomide is an inhibitor of *de novo* pyrimidine synthesis. Leflunomide (Fig. 87.5) is converted into the long-acting active compound A77 1726 (2-cyano-3-hydroxy-N-[4-trifluoromethyl]-butenamide) (Fig. 87.6), a reversible inhibitor of the enzyme dihydroorotate dehydrogenase that is involved in pyrimidine synthesis. Because of this long half-life, therapy with leflunomide is usually started with a loading dose to quickly achieve therapeutic levels. A77 1726 is highly plasma-protein bound and undergoes enterohepatic recirculation.



Leflunomide

FIG 87.5 Leflunomide—chemical structure.



A77 1726

FIG 87.6 A77 1726—chemical structure.

Mechanisms of Action of Leflunomide

By inhibiting pyrimidine synthesis, pyrimidine nucleotide availability becomes insufficient for proliferation of immune-response cells. This deficiency is inadequately replenished by the salvage pathways, rendering cell proliferation inefficient and limiting the clonal expansion of T cells. B-cell proliferation is similarly suppressed with reduction of Cdk2, a cyclin-dependent kinase. Leflunomide also inhibits NF-κB activation. Although the effects of moderate concentrations are reversed by uridine *in vitro*, this reversal does not occur at higher concentrations, suggesting possible involvement of other mechanisms. Leflunomide is known to inhibit tyrosine kinase activity at higher concentrations, although the relevance of this effect to therapeutic concentrations achievable *in vivo* remains questionable.

Adverse Effects

GI symptoms are the most common side effect, and hepatic damage is the most important toxicity. Although there are similarities to the toxicity profile of methotrexate, clinical trials have shown that leflunomide and methotrexate can be safely and effectively given together to patients with RA, but transaminasemia occurs more often than with methotrexate alone.[9,10] Fulminant hepatic failure is rare, but fatal cases have occurred. Skin reactions are mostly minor; however, more serious manifestations, such as Stevens-Johnson syndrome and toxic epidermal necrolysis, have been reported.

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil (Fig. 87.7) is widely used in solid organ transplantation and has also been increasingly employed in treatment of autoimmune diseases. It is rapidly absorbed and hydrolyzed into the active compound, mycophenolic acid, which is a reversible inhibitor of inosine monophosphate dehydrogenase. Since inosine monophosphate dehydrogenase is a key enzyme in the *de novo* synthesis of guanine nucleotides, its inhibition is most significant in T and B lymphocytes, which are reliant on this pathway, as they lack the hypoxanthine-guanine phosphoribosyl transferase salvage pathway. The immunological effects are numerous. DNA synthesis in lymphocytes requires the incorporation of guanine nucleotides so that proliferation of

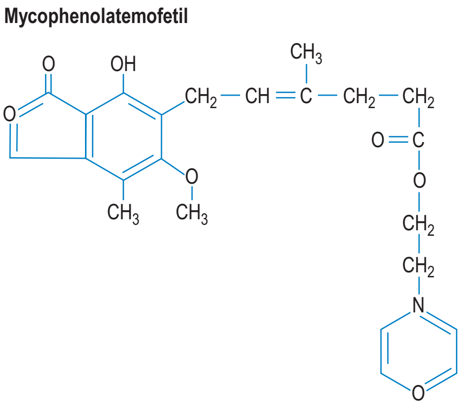


FIG 87.7 Mycophenolate mofetil – chemical structure.

lymphocytes is suppressed. Antibody production and NK-cell activity are also reduced, and *in vitro* cytokine production by activated human mononuclear cells is affected.[11] In addition, delayed-type hypersensitivity responses are suppressed. Although effective in a subset of patients with psoriasis and RA, mycophenolate mofetil has not been widely used in these conditions because other more effective medications are available. It is, however, becoming more popular in the treatment of some diseases, such as myositis, systemic contact dermatitis, severe atopic dermatitis, chronic urticaria, refractory pyoderma gangrenosum, bullous pemphigoid, pemphigus vulgaris, and pemphigus foliaceus, where it is effective with a low risk of side effects.

Adverse Effects

Absolute contraindications for mycophenolate mofetil are drug allergy and pregnancy (Category D). Relative contraindications include lactation; renal, hepatic, or cardiopulmonary disease; and peptic ulcer. It is generally well tolerated when used in autoimmune diseases, such as RA. The most common side effects are nausea, vomiting, abdominal discomfort, diarrhea, fever, headache, skin rash, back pain, and tremor, but these do not usually lead to discontinuation. Rarely reported side effects include leukopenia and other cytopenias, cutaneous and noncutaneous malignancies, and pancreatitis. Toxic doses have not been established for this medication. One patient suffered only moderate leukopenia with no significant GI side effects after ingesting 25g of mycophenolate mofetil. Up to 4 g/day have been used in cardiac and up to 5 g/day in hepatic transplantation patients. However, increased efficacy was not observed above 2 g/day, and patients were more likely to experience GI symptoms and neutropenia at higher doses. For this reason, doses up to 2 g/day are usually employed to treat inflammatory conditions.

HYDROXYUREA

Hydroxyurea is urea with one additional hydroxyl group. It inhibits ribonucleotide reductase, which catalyzes the reduction of ribonucleotides to deoxyribonucleotides, and is thus essential in DNA synthesis. It is effective in the treatment of psoriasis.[12] Hydroxyurea is well tolerated, with the most common side effects being hematological, usually megaloblastic anemia, but also leukopenia and thrombocytopenia. Other significant but rare adverse effects include renal and GI toxicity, a dermatomyositis-like syndrome, leg ulcers, radiation recall, and leukemias.

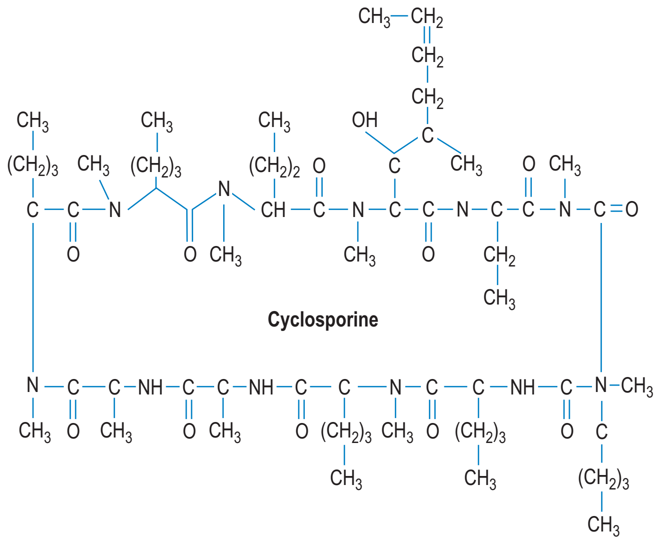

FIG 87.8 Cyclosporine—chemical structure.

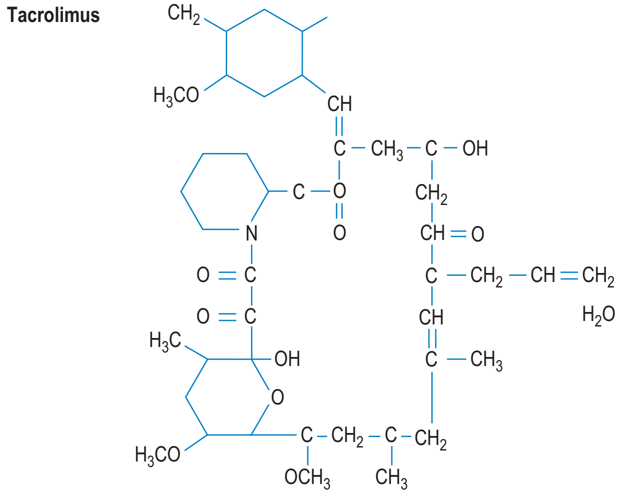

FIG 87.9 Tacrolimus—chemical structure.

ORAL CYCLOSPORINE AND TACROLIMUS (FK506)

Cyclosporine (Fig. 87.8) and tacrolimus (Fig. 87.9) are structurally similar drugs that have been widely used in solid organ transplantation as well as in the treatment of immunological diseases. Cyclosporine has potent inhibitory effects in dampening the production of proinflammatory mediators, such as IL-2, by immunocompetent cells, most importantly T lymphocytes. It does so through binding cyclophilin, which produces a cyclosporine–cyclophilin complex. This complex binds the serine/threonine phosphatase calcineurin.[13] This disrupts the phosphorylation of regulatory proteins for which the nucleated factor of activated T cells (NF-ATs) is a critical component, preventing these proteins from translocating into the nucleus. Thus the transcription of genes, such as *IL-2,* which induces mitogenesis in activated T cells, cannot be effectively activated. A number of other cytokines are affected, including IL-3, IL-6, transforming growth factor (TGF)-β, and interferon (IFN)-γ. Another T cell–specific immunophilin, FK506-binding protein (FKBP), binds tacrolimus to form a FK506-FKBP complex with similar resultant inhibitory activity on calcineurin.[14]

KEY CONCEPT

Cyclosporine: Mechanism of Action

Association with cyclophilin
Formation of cyclosporine–cyclophilin complex
Binds calcineurin
Inactivates calcineurin
Regulatory proteins unable to translocate into nucleus
Transcription of proinflammatory genes affected

Adverse Effects

The most common side effects of cyclosporine are hypertension, hyperkalemia, hypomagnesemia, and hyperlipidemia. More importantly, cyclosporine has well-documented short-term and long-term adverse effects on kidney function.[15] These data come from patients who had received solid organ transplants, most notably renal transplants. In such patients, initial doses of 15–25 mg/kg/day led to a reduction in the glomerular filtration rate (GFR) and rise in serum creatinine in a percentage of patients, as well as histologically proven nephropathy.[16] The pathogenic mechanism of kidney damage is poorly understood but is believed to consist of two phases.[17] The first is a period of partial ischemia secondary to vascular contraction, which is reversible with dose reduction or drug discontinuation. The later, irreversible phase results from chronic scarring of the glomeruli. Treatment recommendations for some diseases, such as psoriasis, have therefore been targeted at much lower maximum daily doses of 5 mg/kg/day, with a reduced dose if creatinine rises 30% above baseline. Otherwise healthy patients treated at these dosage levels have been successfully managed for many years on cyclosporine with no impact on the GFR.[18] Nephrotoxicity has also been a concern during tacrolimus therapy. Other adverse effects include increased rate of infections, malignancy, hepatotoxicity, GI upset, rash, tremor, headache, and insomnia.

TOPICAL PIMECROLIMUS AND TACROLIMUS (FK506)

Tacrolimus is also available in topical formulation. Pimecrolimus is an alternative topical calcineurin inhibitor with similar structure and identical mechanisms of action. The cyclosporine molecule is too large to penetrate skin (1203 Da), whereas tacrolimus and pimecrolimus can, as they are much smaller molecules (804 and 80 daltons [Da], respectively). Both have been approved by the FDA for the treatment of atopic dermatitis but have found widespread use in many other conditions (psoriasis, oral and cutaneous lichen planus, vitiligo, pemphigoid, and pemphigus). They are most often used when long-term topical corticosteroids are contraindicated.

Adverse Effects

The most common side effect is local irritation at the site of application in severely inflamed skin. Therefore initial short-term treatment is often combined with topical steroids. An association with malignancy remains controversial. In 2005, 17 case reports of malignancy in patients using these topicals resulted in a black-box warning, although further studies suggested that the rate of lymphoma from these case reports was lower than the rate observed in the general population in the United States. In 2006, the FDA revised the wording, but a black-box warning about these products remains in place.

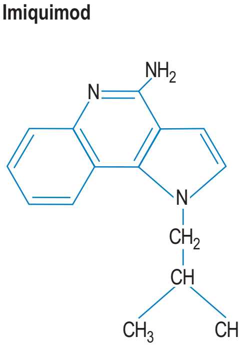

FIG 87.10 Imiquimod—chemical structure.

SIROLIMUS

Sirolimus is a macrolide that binds the cytosolic protein FK-binding protein 12 (FKBP12). In contrast to the tacrolimus–FKBP12 complex, which inhibits calcineurin, the sirolimus–FKBP12 complex directly binds the mammalian target of rapamycin (mTOR) complex1 (mTORC1), thereby inhibiting the mTOR pathway. Thus it inhibits the response to IL-2, blocking activation of T and B cells. It has shown promise in the treatment for systemic lupus erythematosus (SLE); Sjögren syndrome[19]; RA[20]; psoriasis; genetic disorders, such as tuberous sclerosis; and neoplastic disorders, such as Kaposi sarcoma.[21] The main advantage of sirolimus over tacrolimus or cyclosporine is reduced renal toxicity.

IMIQUIMOD

Imiquimod (Fig. 87.10), an imidazoquinoline drug, activates Toll-like receptor (TLR)-7 and possesses both antiviral and antitumor activities.[22] As a cream preparation, it is effective in the treatment of external genital warts caused by infection with human papillomavirus (HPV). Immune amplification responses are induced through stimulation of inflammatory cytokines.[23,24] Production of IFN-α is stimulated, and this suppresses replication of viruses in infected keratinocytes. NK-cell activity is also increased, partly through the induction of oligoadenylate synthase. The increase of dermal IFN-α transcript levels is rapid and dramatic.[25] Other cytokines modulated by imiquimod include TNF-α and IL-12, especially in peripheral blood monocytes.[26,27] The overall effect is a shift from a T-helper-2 (Th2)-cytokine–predominant profile toward a Th1-cytokine–predominant profile. Other conditions where imiquimod is effective include actinic keratosis, herpes simplex, basal cell carcinoma, and molluscum contagiosum.

Adverse Effects

Inflammation at the site of application represents the most common adverse reaction. However, nondermatological side effects, such as fever, fatigue, myalgia, and headache, have also been described.

5-FLUOROURACIL

5-Fluorouracil is a uracil analogue that has two modes of action. First, it inhibits cell proliferation via direct incorporation into RNA causing abnormal base pairing. Second, it binds thymidylate synthetase, blocking the conversion of deoxyuridine monophosphate to deoxythymidine monophosphate, which is essential to DNA synthesis. It may also increase expression of *p53,* a frequently mutated gene in nonmelanoma skin cancers.[28] It can be administered topically, intramuscularly, or intravenously. In topical form, its main uses are to treat actinic keratosis, superficial basal cell carcinoma, Bowen disease, keratoacanthoma, porokeratosis, and verruca vulgaris. However, intravenous treatment of recalcitrant psoriasis, mycosis fungoides, and scleroderma has also been reported.

Adverse Effects

Topical application is associated with an irritant dermatitis, but this is also seen as a marker of clinical efficacy. Parenteral administration for inflammatory conditions is not widespread; adverse effects from parenteral administration are more severe and include clinically significant bone marrow suppression, GI toxicity, and cutaneous reactions.

GLATIRAMER

Glatiramer acetate is a random polymer of glutamic acid, lysine, tyrosine, and alanine, the four amino acids found in myelin basic protein (MBP). The mechanism of action for glatiramer is unknown, but its similarity in structure to MBP may allow it to act as a decoy for immune targeting of myelin. It may also induce expression of glatiramer acetate–specific suppressor T cells, and these have been shown to be present in animal models. In contrast to imiquimod, glatiramer shifts the population of T cells from proinflammatory Th1 cells to regulatory Th2 cells that suppress the inflammatory response. It is FDA approved for the treatment of adults with relapsing–remitting multiple sclerosis (MS), even after only one event.

Adverse Effects

Absolute contraindications include allergy to glatiramer or to mannitol. It is pregnancy Category B, but it is unknown if the drug is secreted in breast milk. The drug is given via subcutaneous injection, and the most common adverse effects are injection site reaction, flushing, rash, dyspnea, and transient chest pain.

FINGOLIMOD (FTY720)

Fingolimod is a relatively new immunomodulator for treating MS. It is a structural analogue of sphingosine and is phosphorylated intracellularly by sphingosine kinases.[29] Signaling via one of the sphingosine 1 phosphate receptors, S1PR1, it is believed to prevent migration of lymphocytes by halting their ability to leave lymph nodes. However, fingolimod has also been reported to act as a cPLA2 inhibitor,[30] a cannabinoid receptor antagonist,[31] and a ceramide synthase inhibitor.[32] So far, the FDA has only approved it for use in MS. However, it has also shown promise in murine models of SLE and RA, with reduced mortality from lupus nephritis[33] and improvement in arthritis, respectively.[34] It also has a potential role in the treatment of cutaneous inflammatory conditions, such as psoriasis and atopic dermatitis.[35]

Adverse Effects

The most common side effects are minor and include headache and fatigue. However, fingolimod has also been associated with serious infections, an increased rate of skin cancers, bradycardia, and one case of focal hemorrhagic encephalitis.

CONCLUSIONS

The field of small molecule immunomodulators contains both traditional and new molecules. The traditional molecules come with a long history of efficacy and side-effect data, and this allows us to safely and accurately utilize these therapies. Despite the introduction of biologics, traditional small-molecule agents, such as methotrexate and cyclosporine, are both clinically efficacious and cost-effective and thus remain the workhorses of our modern pharmaceutical armamentarium. However, as our understanding of the pathways involved in inflammation evolve, our therapeutics are also refined, allowing the production now, for example, of topically effective calcineurin inhibitors, such as tacrolimus and pimecrolimus, which avoid the adverse effects of systemic cyclosporine or topical steroids, and sirolimus, which reduces toxicity profiles of systemic FKBP2 signaling. In addition, newer agents, such as glatiramer and fingolimod, allow treatment of MS, a disease recalcitrant to more traditional therapies, and, although not currently being used in other inflammatory disorders, have shown promise in animal models. The field of small-molecule immunomodulators therefore remains one of both current clinical relevance and continuing, exciting new developments.

ON THE HORIZON

Refinement of our understanding of the pathways and actions of receptors targeted by our current medications is the key to producing more elegant therapies.

Separating therapeutic effects from the pathways leading to side effects would enable much safer and more tolerable small-molecule medications.

Better understanding of the dysregulation that occurs in inflammatory conditions, and the activation of the immune system will be essential to ensuring the efficacy of such new modalities.

The challenge in the next 5–10 years is to continue this refinement in the targeting of small molecules. Many of the agents we currently use target early parts of pathways or indiscriminately trigger multiple receptors. This leads to a greater range of side effects and thus limits our ability to reach adequate dosing levels. A prime example of this is methotrexate, which leads to increased adenosine levels and thus triggers all four adenosine receptors. By developing more selective molecules targeting, for instance, just the adenosine A_{2A} receptor, not only would we avoid the side effects attributable to other adenosine receptors, we might also avoid the effects of methotrexate on bone marrow and mucous membranes via inhibition of dihydrofolate reductase. In other medications, more specific targeting of pathways may similarly reduce side effects and make for more effective therapeutics. This will require a better understanding of the immune system and its dysregulation in disease, as well as development and application of these medications to clinically relevant models

MULTIPLE-CHOICE QUESTIONS

1. Which of the following medications' antiinflammatory effects may be reduced in heavy coffee drinkers?
   A. Methotrexate
   B. Azathioprine
   C. Mycophenolate mofetil
   D. Cyclosporine
   E. Tacrolimus

2. Which of the following medications is pregnancy Category B?
   A. Methotrexate
   B. Mycophenolate mofetil
   C. Glatiramer
   D. Azathioprine
   E. 5-Florouracil

3. In which of the following medicines should glucose-6-phosphate dehydrogenase (G6PD) screening be considered before use?
   A. Methotrexate
   B. Azathioprine
   C. Sulfasalazine
   D. Mycophenolate mofetil
   E. Imiquimod

Protein Kinase Antagonists in Therapy of Immunological and Inflammatory Diseases

Arian Laurence, Massimo Gadina, John J. O'Shea

Reversible phosphorylation is one of the major mechanisms controlling protein activity in all eukaryotic cells and, as such, is involved in all fundamental cellular processes, including cell cycle and cell growth, cell shape and movement, metabolism, differentiation, and apoptosis. This covalent modification is a major means for transmitting information from outside the cell and between the subcellular components within the cell. Phosphorylation is a major mechanism underlying normal signaling, as exemplified by insulin and other growth factors, but in addition, the importance of protein phosphorylation is supported by evidence that mutations and dysregulation of protein kinases play causal roles in human disease. This is especially true in cancer, in which mutant protein kinases or their upstream activators function as oncogenes.

From the point of view of an immunologist, protein phosphorylation is also the major mechanism by which immune receptors, including the T-cell receptor (TCR), B-cell receptor, and natural killer (NK) cell receptor and Fc receptors, trigger signaling. As discussed in Chapter 4, the first step in signaling by multichain immune recognition receptors (*e.g.*, the aforementioned receptors) is tyrosine phosphorylation of the receptor itself and adapter molecules, such as linker of activated T cells (LAT), mediated by Src family protein tyrosine kinases (PTKs). This leads to the recruitment of PTK members spleen tyrosine kinase (Syk) and Zap70 followed by phosphorylation of adapters, such as SH2 domain-containing leukocyte phosphoprotein of 76 kDa (SLP-76) and the activation of Tec family PTKs. These initial steps trigger the activation of serine-threonine kinases, including the mitogen-activated protein kinases (MAPKs) and protein kinase C (PKC) family (Fig. 88.1). We now know a great deal of details about how the cascade of protein phosphorylation links events at the plasma membrane to calcium modulation, cytoskeletal rearrangement, gene transcription, and other canonical features of lymphocyte action (Chapter 12).

Similarly, a critical first step in signaling by many cytokine receptors is the activation of phosphorylation. The receptors for classical growth factor cytokines, including stem cell factor and platelet-derived growth factor (PDGF) are receptor tyrosine kinases (RTKs), whereas the receptors for transforming growth factor family cytokines are receptor serine–threonine kinases. Type I and II cytokine receptors signal via the activation of receptor-associated Janus kinases (JAKs; see below, Table 88.1 and Table 88.2) (Chapter 9). Other cytokines like interleukin (IL)-1 and tumor necrosis factor (TNF) initiate signaling in a kinase-independent manner but, nonetheless, signal through kinase cascades to exert their effects. It is clear that many aspects of protein phosphorylation are of major importance in immune and inflammatory mechanisms.

The nonredundant functions of various kinases in different immune cells are exemplified by both studies in knock-out mice and humans with mutations. On the basis of these findings, targeting protein kinases has been proposed to be a useful strategy in the development of novel immunosuppressant drugs and is one of the most active areas of pharmaceutical drug development (Table 88.3), with much of the impetus coming from oncology. The field is so vast that it is impractical to comprehensively review all this information in one chapter; therefore we will focus both on important historical precedents in the field and then discuss drugs and targets that are most immunologically relevant. We will start by briefly reviewing some of the basics of kinase biochemistry.

STRUCTURE AND FUNCTION OF PROTEIN KINASES

KEY CONCEPTS

Kinase Families

- 518 kinases in the genome
- 90 protein tyrosine kinases (*e.g.*, Janus kinases [JAKs])
- 400 protein serine/ threonine kinases:
  - AGC kinase family (*e.g.*, protein kinase B/AKT)
  - CAMK kinase family (*e.g.*, calmodulin-dependent kinase)
  - CMGC kinase family (*e.g.*, MAP kinases: ERK, JNK, p38)
  - STE kinase family (*e.g.*, MAPK kinases, MAPKK kinases)
  - TKL kinase family (*e.g.*, IRAK)
  - Others: casein kinase family, GYC kinase family, IKK family

Protein kinases or phosphotransferases catalyze the transfer of the γ-phosphate from a purine nucleotide triphosphate (*i.e.*, adenosine triphosphate [ATP] and guanosine triphosphate [GTP]) to the hydroxyl groups of their protein substrates. They generate phosphate monoesters by using protein alcohol groups (on serine and threonine residues) and/or protein phenolic groups (on tyrosine residues) as phosphate acceptors. Thus protein kinases can be classified by the amino acid substrate preference: serine/threonine kinases, tyrosine kinases, and dual kinases (*i.e.*, both serine/threonine and tyrosine residues can be phosphorylated).

TABLE 88.2 The JAK Family of Tyrosine Kinases

Gene	Murine Phenotype Associated With Gene Deletion	Associated Receptor
Jak1	Perinatal lethality, block in thymocyte development	Many including IL-7R and IFNRs
Jak2	Embryonic lethality due to anemia	Erythropoietin receptor
Jak3	T-, B-, and NK-cell lymphopenia, SCID phenotype	Common gamma chain receptor
Tyk2	Failure to clear *Toxoplasma,* reduced arthritis	IL-12/23 receptor

JAK, Janus kinase; IL, interleukin; IFNR, interferon receptor; NK, natural killer; SCID, severe combined immune deficiency.

Almost all protein kinases have catalytic domains that belong to a single eukaryotic protein kinase (ePK) superfamily. The common evolutionary ancestry of the kinase domain (also known as the *catalytic domain*), which consists of 250–300 amino acid residues, manifests as a highly conserved three-dimensional structure. In the human genome, there are 518 kinases, which are divided into eight major groups, in totality, representing 1.7% of the human genome. The PTK family has 90 members, one-third of which are RTKs, and the remainder are cytoplasmic proteins that typically function in close proximity to, and downstream of, receptor–ligand complexes.

In terms of its catalytic role, the kinase domain has three functions: the binding of the ATP (or GTP) phosphate donor as a complex with a divalent cation (usually Mg^{2+} or Mn^{2+}), the

TABLE 88.3 Selected Kinase Inhibitors and Related Drugs

Mechanism	Compound	Kinase Inhibited	Comments
Direct binding to the kinase	Imatinib	Kit, platelet-derived growth factor (PDGFR), and Abl	Approved for treatment of chronic myeloid leukemia (CML), eosinophilic leukemia, and gastric stromal tumors Used in the treatment of chronic sclerodermatous graft-versus-host disease (GvHD) Under evaluation in multiple types of cancer and in combination with other cancer drugs
	Ponatinib		US Food and Drug Administration (FDA) approved for the treatment of CML and PH + acute lymphoblastic leukemia (ALL) Phase II trial for acute myeloid leukemia (AML) and a number of solid cancers
	Nilotinib		Approved for Philadelphia chromosome-positive CML; in Phase II trials for AML and ALL
	Radotinib	PDGFR and Abl	FDA approved for the treatment of CML
	Dasatinib	Multiple Src family tyrosine kinases, including Abl	Approved for treatment of adult CML and Philadelphia chromosome positive ALL Phase III trial for prostate cancer Phase II trial for CLL, Sarcomas
	Bosutinib		Approved for the treatment of imatinib-resistant CML Phase II trial for glioblastoma
	Ibrutinib	Btk, Itk	FDA approved for the treatment of CLL, mantle-cell lymphoma (MCL), lymphoplasmacytic lymphoma (LPL) Phase III trial for the treatment of diffuse large B-cell lymphoma (DLBCL), posttransplantation lymphoproliferative disease (PTLD), pancreatic cancer Phase II trial for GvHD
	Spebrutinib		Phase II trial for RA, Phase I trial for CLL, non-Hodgkin lymphoma (NHL)
	Acalabrutinib		Phase III trial for CLL, phase II trial for rheumatoid arthritis (RA) FDA approved for the treatment of mantle cell lymphoma (MCL)
	Lapatinib	ErbB-2 and epidermal growth factor receptor (EGFR) kinases	Approved for treatment of breast cancer Minor survival improvement in head and neck cancer Phase III trials for brain metastasis
	Afatinib		FDA approved for treatment of non–small cell lung carcinoma (NSCLC) Phase III trial for breast cancer and head and neck cancer
	Neratinib		Phase III trial for treatment of breast cancer Phase II trial for NSCLC
	Gefitinib		Approved for use in NSCLC as a first-line therapy by FDA Successful phase III study in esophageal cancer
	Erlotinib	HER1/EGFR, JAK2	Approved for treatment of pancreatic cancer and certain categories of NSCLC In phase II and III trials for various other cancers, including myeloproliferative disease
	Vandetanib	VEGFR-2, EGFR, RET, and ErbB-1 tyrosine kinases	Approved in 2011 for certain types of progressive medullary thyroid cancer Phase II trial for small cell lung cancer
	Tivozanib	Vascular endothelial growth factor receptor (VEGFR) kinases	Phase I trial for solid tumors
	Lenvatinib		FDA approved for thyroid cancer and under phase III trials for hepatocellular cancer
	Regorafenib		FDA approved for the treatment of Colorectal cancer and gastrointestinal stromal tumor (GIST) Phase III trials for hepatocellular cancer
	Brivanib	VEGFR-2, FGFR	Orphan drug status for the treatment of hepatocellular cancer
	(N)intedanib	VEGFR, PDGFR, FGFR	Approved for the treatment of idiopathic pulmonary fibrosis and NSLCLC adenocarcinoma In phase III trials for the treatment of ovarian and colorectal carcinoma

Continued

TABLE 88.3 Selected Kinase Inhibitors and Related Drugs—cont'd

Mechanism	Compound	Kinase Inhibited	Comments
	Cabozantinib	VEGFR, MET, RET	FDA approved for treatment of thyroid cancer Phase III registration for hepatocellular cancer
	Axitinib	VEGFR1, 2 and 3, Abl (T315I), PDGFR-β and Kit	Approved for treatment of renal cancer; has orphan drug status for follicular, medullary, and anaplastic thyroid carcinoma and metastatic or locally advanced papillary thyroid cancer Effective in imatinib resistant CML associated with the T315I mutation
	Sunitinib	Inhibits multiple receptor tyrosine kinases (RTKs), including PDGFR3-alpha, PDGFR-β, VEGFR1, VEGFR2, VEGFR3, Kit, Flt3, CSF-1R, and RET	For treatment of gastrointestinal stromal tumor after disease progression on or intolerance of imatinib and for treatment of advanced renal cell carcinoma and pancreatic neuroendocrine tumors Completed phase II trials in NSCLC and breast cancer Potential benefit in Flt3 + AML
	Sorafenib	Dual-specific inhibitor blocking both tyrosine and serine/threonine kinases, including RAF kinase, VEGFR-2, VEGFR-3, PDGFR-B, KIT, Flt3, and RET	FDA approved for treatment of advanced renal cell carcinoma, thyroid cancer, and hepatocellular cancer In phase II trials for AML, ALL, CML, myelodysplastic syndrome (MDS), neurofibromatosis, portal hypertension
	Pazopanib	Inhibits multiple RTKs, including PDGFR3-α, PDGFR-β, VEGFR1 VEGFR2, VEGFR3, cKIT, Lck, c-FMS, FGFR-1, and FGFR-3	Approved for treatment of advanced renal cell cancer and soft tissue sarcoma Mixed results as a treatment for age related macular degeneration when used topically
	Entrectinib	ALK, TrkA, TrkB, TrkC, ROS1	Phase II trial for colorectal cancer, NSCLC Phase I trial for neuroblastoma
	Crizotinib	ALK, c-Met	Approved for treatment of ALK-positive NSCLC Phase II trial for anaplastic lymphoma kinase (ALK)–positive lymphoma
	Filgotinib	JAK 1	Completed phase IIb studies in RA Completed phase II studies in Crohn disease
	ABT-494		In phase III trial for RA and phase II trial for Crohn disease
	Ruxolitinib	JAK1 and JAK 2	FDA approved for myeloproliferative diseases In trials for treatment of GvHD
	Baricitinib		Completed phase III trials for rheumatoid arthritis Completed phase IIb trials in psoriasis
	Gandotinib (LY2784544)		In phase II clinical trials for myeloproliferative disorders
	Oclacitinib		FDA approved for the treatment of canine allergic dermatitis
	AC-410		In phase I clinical trials for autoimmune and myeloproliferative syndrome
	Tofacitinib	JAK3, JAK1, (JAK2)	FDA approved for the treatment of RA Completed phase III trials for the treatment of ulcerative colitis (UC)and psoriasis
	Peficitinib		Phase IIb for RA and UC
	Decernotinib	JAK 3	Completed phase III studies in the treatment of RA
	Momelotinib	JAK1, JAK2, IKKe, and TBK1	In phase III trials for pancreatic adenocarcinoma
	TG02/ SB-1317	JAK2, Flt3, CDK1, -2, -7, -9	In phase I clinical trials for ALL, AML, CLL
	Fedratinib	JAK2, Flt3, RET	In phase II trial for chronic beryllium disease
	AT-9283	JAK2, JAK3, aurora A/B kinase, highly active against the Gleevec-resistant T315I Abl mutation	Completed phase I trial for solid tumors in children
	Lestaurtinib	Flt3, TrkA, and JAK2	In phase III clinical trials for treatment of patients with AML who have an Flt3-activating mutation at first relapse from standard induction chemotherapy In phase II trials for psoriasis and pancreatic cancer

TABLE 88.3 Selected Kinase Inhibitors and Related Drugs—cont'd

Mechanism	Compound	Kinase Inhibited	Comments
	Quizartinib	Class III receptor tyrosine kinases (Flt3, Kit, CSF1)	Completed phase II clinical trial for drug-resistant AML
	Fostamatinib	Syk, Flt3	Phase III for idiopathic thrombocytopenic purpura (ITP) Phase II for immunoglobulin A (IgA) nephropathy Failed phase III for RA, phase I for GvHD
	PRT-062607/ BIIB057/ P505-15	Syk	In phase I clinical trials for RA, CLL, NHL; preclinical for systemic lupus erythematosus (SLE)
	R-348	JAK/Syk	In phase II trials for ocular GvHD
	Vemurafenib	BRAF	FDA approved for the treatment of BRAF mutated melanoma; phase II trial for colorectal cancer and myeloma
	Dabrafenib		FDA approved for the treatment of BRAF mutated melanoma
	Selumetinib	MKK family	Phase III trial for NSCLC and thyroid cancer Phase II for colorectal cancer and biliary cancer
	Cobimetinib		FDA approved for the treatment of melanoma Phase II trial for the treatment of breast cancer and Langerhans cell histiocytosis
	Trametinib		FDA approved for the treatment of BRAF mutated melanoma in combination with dabrafenib
	Binimetinib		Phase III trial for the treatment of BRAF mutated melanoma
	PD-325901		Phase II trial for neurofibromatosis
	CC 90003	ERK	Phase I trial for solid tumors
	XG102	JNK	Phase III trial for ocular inflammation and sensorineural hearing loss
	RES-529	AKT, MTOR, VEGFR	Phase I trial for age-related macular degeneration
	Uprosertib	AKT	Phase II trial for AML, solid tumors
	MK-2206		Phase II trial for solid and hematological malignancies
	AZD-5363		Phase II trial for breast and gastric cancer
	Pexidartinib	CSF-1R, Kit	Phase II trial for pigmented villonodular synovitis
	AZD 2014	MTORC1 and C2	Phase II trial for DLBCL and solid tumors
	CC 223		Phase II trial for NHL and solid tumors
	Sotrastaurin	PKC	Phase II trial for DLBCL
	Ribociclib	CDK4,6	Phase III trial for breast cancer Phase II trial for gastrointestinal cancer
	Palbociclib		FDA approved for the treatment of breast cancer Phase III trial for NSCLC
	Buparlisib	PI3K	Phase III trial for breast cancer
	Bardoxolone	IKbK, COX2, NOSII, STAT3	Phase II trial for diabetic neuropathy and pulmonary hypertension
	Fasudil	ROCK1/ ROCK2	Phase III for Raynaud phenomenon and scleroderma completed
	KD-025	ROCK2	Phase II for psoriasis vulgaris Phase II for idiopathic pulmonary fibrosis
Indirect binding to kinase	Sirolimus (Rapamycin)	mTORC1	FDA licensed for use in solid organ and bone marrow transplantation
	Everolimus		FDA licensed for use with cyclosporine in cardiac and renal transplantation FDA licensed for use in neuroendocrine tumors and renal cell carcinoma
	Temsirolimus		FDA licensed for use with MCL, renal cancer
	Ridaforolimus		Phase II trial for coronary artery restenosis
Monoclonal antibodies binding to receptor tyrosine kinases	Trastuzumab	EGFR	FDA licensed for use in HER2/neu positive breast carcinoma and metastatic gastric cancer
	Cetuximab		FDA licensed for use in relapsed colorectal and head/neck cancers
	Bevacizumab	VEGF—prevents binding to its receptor (Flt-1)	FDA licensed for use in metastatic breast and colorectal cancers, glioblastoma, and NSCLC (non-squamous cell histology) in combination with traditional chemotherapy
Other mechanisms of action	Barasertib	Aurora kinase B (functions in the attachment of the mitotic spindle to the centromere)	Disrupts mitosis and cellular division in tumor cells; in phase III clinical trials for AML

binding of the protein substrate, and the transfer of the γ-phosphate from ATP or GTP to the protein substrate. Despite the huge number of serine/threonine and tyrosine kinases, there is evidence of a common ancestor, and this is reflected in structural similarities, particularly in the active (ATP bound) confirmation. The major kinase domains of all typical protein kinases consists of two lobes (N-lobe and C-lobe) that surround the nucleotide binding site[1] (Fig. 88.2). The smaller N-lobe consists of a cluster of β-pleated sheets with a single α helix. The larger C-lobe is made up of α helices. Within the C-lobe lies the substrate-binding site, typically a groove on the surface. A hinge region connects the two lobes. The hinge together with two loops emerging from each lobe form the ATP-binding pocket: the primary target for most kinase inhibitors. In many protein kinases, a loop emerging from the C-lobe must be phosphorylated for the kinase to be fully active (see Fig. 88.2). This is known as the *activation loop.* Substrates of PTKs often include the activation loop of downstream kinases, creating signaling cascades of proteins, which, in turn, phosphorylate each other; examples include the MAPKs (Fig. 88.3).

THE DISCOVERY OF KINASE INHIBITORS

Given that protein kinases bind ATP, the notion that therapeutically useful kinase inhibitors could be generated was initially met with some skepticism. First, as there are more than 500 human kinases, many of which serve critical cellular functions, would it really be possible to attain the specificity needed? Second, protein kinases are not the only kinases—there are lipid kinases and nucleotide kinases, as well as many other ATP-binding

FIG 88.2 Crystal Structure of the Janus Kinase 3 (JAK3) Domain Complexed With Staurosporine (pdb Accession Code 1YVJ). This structure captures the active conformation of JAK3 with both active loop tyrosine residues phosphorylated (green). The molecule can be described as halves, with the N-terminal lobe presented in blue and the C-terminal domain in red. These are linked by a hinge region that forms part of the active site. Highlighted in purple within the active site is the gatekeeper residue. Bound within this site is an analogue of the inhibitor staurosporine, and its proximity to the "gatekeeper" residue highlights why this residue and this region are critical for the specificity of inhibitors for individual protein kinases.

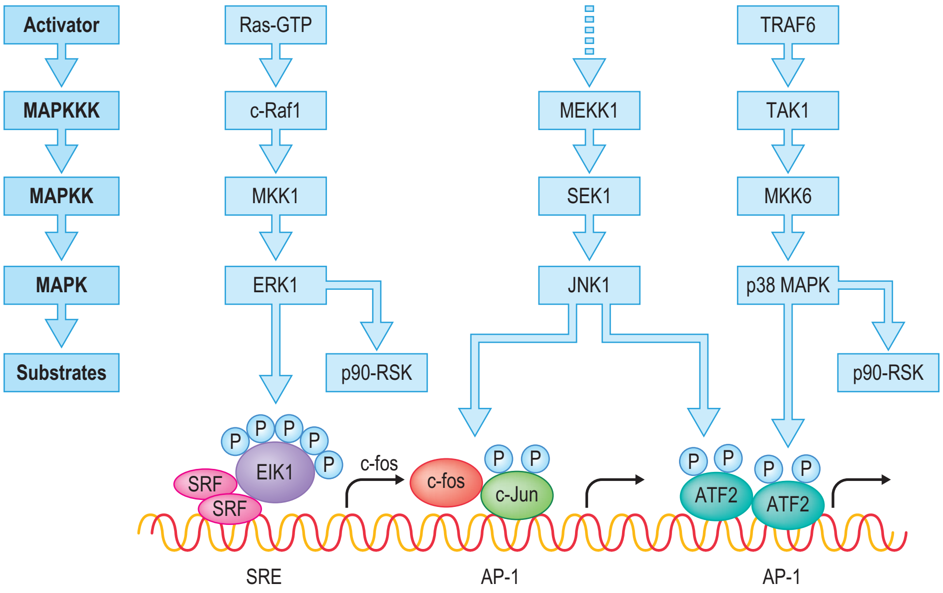

FIG 88.3 A Summary of the Mitogen-Activated Protein Kinase (MAPK) Signal Transduction Pathways. Examples of receptors that activate Ras include the interleukin (IL)-2 and T-cell receptor (TCR). Examples of receptors that activate tumor necrosis factor receptor–associated factor 6 (TRAF6) include the IL-1 receptor.

proteins, all of which share structural similarities with PTKs. Third, despite the many potential ways of designing a small-molecule kinase inhibitor, in practice, the majority work by sitting within the ATP-binding pocket.[2] *A priori* then, one might conclude that it would be impossible to generate an antagonist that did not target some other essential ATP-dependent process. Fortunately though, this skeptical view does not reflect reality.

THERAPEUTIC PRINCIPLES

Protein Kinase Inhibitors As Drugs

- Drugs can inhibit protein kinases with a high degree of specificity.
- Multi-kinase inhibitors can be well tolerated and be more efficacious than single kinase inhibitors (*e.g.*, second-generation Abl kinase inhibitors).
- Conversely, unacceptable toxicity has limited the creation of clinical inhibitors to particular kinase members (*e.g.*, p38 MAPK inhibitors).

Imatinib and Other First-Generation Protein Tyrosine Kinases Inhibitors

The first protein kinase inhibitor approved by the US Food and Drug Administration (FDA) is imatinib (see Table 88.3). The mutated form of the Abl tyrosine kinase BCR-Abl represents a fusion protein that is the result of a chromosomal translocation (Philadelphia chromosome) observed in patients suffering from chronic myeloid leukemia (CML). The pathognomonic presence of BCR-Abl in CML has led to it becoming one of the most intensively studied PTKs. The fusion protein consists of an oligomerization domain, a PH domain, and a Dbl/cdc24 guanine nucleotide exchange factor homology domain that contains the N-terminal breakpoint cluster region (BCR) of the protein. The Abl half of the fusion protein contains a tyrosine kinase domain, a Src homology 2 (SH2) domain, and a DNA-binding domain, together with nuclear localization and nuclear export motifs. The Abl kinase is constitutively active within the fusion protein and has been implicated in initiating numerous signaling pathways that mediate cell survival and proliferation. In view of this, and the essential requirement for BCR-Abl kinase activity in CML, it was thought to be an ideal target despite the aforementioned caveats with targeting protein kinases. As predicted, imatinib has revolutionized the treatment of CML. This inhibitor has been remarkably successful in arresting the progression of the CML but is also well tolerated with acceptable side effects.[3]

Although conservation of the kinase ATP-binding pocket has posed a potential problem for designing kinase inhibitors, in practice, this has not happened for several reasons. Although different kinases may be structurally similar in an active ATP-bound conformation, the inactive conformation is substantially less frequent and can be used to generate selective inhibitors.[4] The ATP-binding region is made up of six polar amino acid residues that are invariant across whole families of kinases; similarly, there are numerous lipophilic residues that are highly conserved. In addition, this critical region contains an amino acid whose amide carbonyl binds to N-6 of adenine in the active conformation. The side chain of this amino acid sticks into the reaction pocket in the inactive state and, for this reason, is referred to as "the gatekeeper residue."[5] As the side chain is not involved in direct ATP binding, it varies across kinases, and variation of this gatekeeper residue is exploited by a number of inhibitors that are able to bind the inactive conformation of specific kinases. In the case of Abl kinase, the gatekeeper residue is threonine, which binds directly to a methyl group of the phenyl ring of the Abl kinase inhibitor imatinib.[4] Across the collective kinase superfamily, almost any amino acid can appear as the gatekeeper, although in practice, it is typically a bulky nonpolar residue (methionine, tyrosine, phenylalanine, lysine).[5] In principle, as more detailed structural information emerges from the many protein kinases, capitalizing on subtle differences in structure is expected to lead to the discovery of novel agents with improved potency and specificity. For instance, cyclin-dependent kinase 2 (CDK2) contains an additional pocket on its C-lobe next to the ATP-binding pocket.[6] Several CDK2-specific inhibitors exploit this by binding to both pockets.

Of further structural significance is the emergence of tumor drug resistance in response to the chronic use of protein kinase inhibitors. Mutant forms of BCR-Abl, Kit, and epidermal growth factor receptor (EGFR) have been associated with loss of drug activity and disease relapse. Interestingly, one of the most common sites of mutation is the otherwise conserved "gatekeeper residue." The appearance of such mutations that cause resistance to imatinib have led to the need for other drugs with broader activity against a number of kinases. Thus in the setting of oncology, "multikinase" inhibitors, including dasatinib and sunitinib, have now entered clinical practice and have been approved by the FDA. Although a major problem in the treatment of malignancy, this is less likely to be an issue in the treatment of autoimmune disease; nonetheless, drugs used for oncological indications often end up being quite useful in the treatment of autoimmunity. Such precedents include cyclophosphamide, azathioprine, and methotrexate. Therefore it is not unreasonable to speculate that a number of the kinase inhibitors developed as anticancer agents may ultimately be used to treat inflammatory or immunological diseases.

An unexpected finding for a clinically well-tolerated inhibitor, which was originally thought to be a highly specific inhibitor for Abl kinase, was the realization that imatinib has activity against several other PTKs.[3] Consequently, it has been found to be useful in the treatment of a number of cancers that do not have abnormal Abl kinase activity. Imatinib has been used to treat gastrointestinal (GI) stromal tumor and hypereosinophilic syndrome through its effects on Kit and PDGFR-FIPIL1 kinases, respectively. In spite of efforts to develop highly specific kinase inhibitors, there is increasing evidence that a partial inhibition of multiple kinases is potentially less toxic than originally feared and may be important for the efficacy of many inhibitors. Second-generation Abl inhibitors, including dasatinib and bosutinib, are less selective than imatinib. This lack of specificity may contribute to their improved response rates in the treatment of CML.[7] With respect to immune-mediated diseases, imatinib is used in the clinic for the treatment of fibrotic diseases, including skin fibrosis associated with chronic graft-versus-host disease (GvHD).[8] At the time of writing, there are >20FDA-approved small molecule kinase inhibitors, most which are approved for oncological indications. In addition, there are numerous other kinase inhibitors in clinical trial or development (summarized in Table 88.3). Besides small-molecule direct inhibitors of kinases, which typically block the ATP-binding pocket, there are several alternative strategies. These include small inhibiting RNA to block protein expression of the kinase Syk (Excellair; ZaBeCor Pharmaceutical Co., Bala Cynwyd, PA), inhibition of associated proteins required to activate the target kinase as in the rapamycin derivatives and the use of monoclonal antibodies (mAbs) that inhibit ligand-dependent activation of transmembrane receptor kinases. These mAbs include and target the designated RTK: bevacizumab (vascular endothelial growth factor receptor [VEGFR]), ranibizumab (VEGFR), cetuximab (epidermal growth factor receptor [EGFR]), pertuzumab (human epidermal growth factor receptor [HER]), and trastuzumab (HER2/neu).

TARGETING CYTOKINE SIGNALING BY INHIBITING JANUS KINASES: TOFACITINIB, RUXOLITINIB, AND RELATED COMPOUNDS

Cytokines regulate growth, survival, development, and differentiation of immune cells. Their importance in driving inflammatory and immunological responses has already made them attractive targets as antiinflammatory and immunosuppressive agents. As indicated above, a large subset of cytokines (roughly 60) signal through Janus kinases (JAKs) (see Table 88.2). The essential function of JAKs was documented by knock-out mice and by identifying mutations in patients with immunodeficiencies. Specifically, mutation of *JAK3* results in a severe combined immune deficiency (SCID), characterized by an almost complete absence of T cells and NK cells with defective B cells. This phenocopies deficiency of the cognate receptor that associates with JAK3, the IL-2 receptor common γ chain, cγc (encoded by *IL2RG*), mutation of which underlies X-SCID (see Table 88.1; Fig. 88.4). The profound, but selective, phenotype associated with JAK3 deficiency led to the suggestion that targeting JAKs might be a strategy for the development of a new class of immunomodulatory drugs. There are now several FDA-licensed JAK inhibitors for the treatment of immune and neoplastic diseases, and more are in clinical trials.

Tofacitinib, formerly designated CP-690,550, was one of the first JAK inhibitors to enter the clinic. It inhibits JAK3 and JAK1 and to a lesser extent JAK2, but has little effect on TYK2.[9] Consequently, tofacitinib potently inhibits cγc cytokines but also blocks interferon (IFN)-γ, interleukin (IL)-6, and to a lesser extent

FIG 88.4 **Signal Transduction Pathways Stemming From the Interleukin (IL)-2 Receptor in T Cells Culminating in the Activation of the Mammalian Target of Rapamycin (mTOR) Serine/Threonine Kinase.** Tyrosine kinases are indicated in red, and serine/ threonine kinases are indicated in blue.

IL-12 and IL-23. Functionally, tofacitinib inhibits T-helper 1 (Th1) cells and Th2 differentiation, as well as pathogenic Th17 cells.[9] In addition to inhibiting adaptive immune responses, tofacitinib appears to inhibit innate immune responses as well.[9] Tofacitinib passed phase III trials for the treatment of methotrexate-resistant rheumatoid arthritis (RA) and was FDA approved for this indication in 2012.[10] It completed phase III trials in both ulcerative colitis and psoriasis with successful results.[11] Other diseases in which tofacitinib is being studied include ankylosing spondylitis and juvenile idiopathic arthritis. Tofacitinib has been used in the treatment of alopecia areata, vitiligo, and atopic dermatitis.[11] A variety of additional inhibitors that target JAK3, including decernotinib, peficitinib, and R-348 (Rigel), are under development or in clinical trials (see Table 88.3).

As gene targeting of *Jak2* in mice was embryonically lethal, it was initially thought that inhibition of JAK2 should be avoided. However, the discovery that gain-of-function mutations of *JAK2* underlie primary polycythemia and myelofibrosis led to the idea that pharmacologically targeting JAK2 could be useful. The JAK1/JAK2 inhibitor ruxolitinib was the first JAK inhibitor for the treatment of myelofibrosis to be approved by the FDA in 2011 and was subsequently approved for the treatment of primary polycythemia in 2014.[11] As cγc cytokines employ both JAK1 and JAK3 for signaling, it might be expected that ruxolitinib and tofacitinib might block some of the same cytokines. It is therefore of interest to note that in a phase II study in RA, ruxolitinib was as efficacious as tofacitinib.[12] A number of novel JAK1/JAK2 inhibitors under development both for the treatment of myeloproliferative and inflammatory diseases. The JAK1/JAK2 inhibitors baricitinib, filgotinib, and AC-410 (Daiichi Sankyo, Tokyo, Japan) all are in trials for the treatment of RA (see Table 88.3).

The side effects of JAK inhibitors include infection, including serious infections, anemia, and leukopenia, presumably related to JAK2 inhibition and interference with cytokines, such erythropoietin, IL-11, and colony-stimulating factors.[11] Little reduction in CD4 T cells has been seen, but significant reduction in NK cells and CD8 T cells does occur; just how significant this will be in terms of infection risk remains to be determined.[11]

TARGETING ANTIGEN RECEPTOR SIGNALING

The first event in TCR signaling is the activation of the Src family kinase Lck (see Fig. 88.1), making it an attractive target as a therapy for autoimmune diseases and transplant rejection. Several Lck inhibitors have been developed and showed promise in preclinical models of allograft rejection and autoimmunity, although at the cost of inducing progressive lymphopenia. This is consistent with the finding that induced deficiency of Lck in mice leads to a progressive lymphopenia.[13] Despite considerable effort, the discovery of a selective Lck inhibitor suitable for use as an immunosuppressive agent remains elusive. Lck activation leads to the recruitment of a second round of tyrosine kinases to the TCR complex; these include Zap70 or Syk. Deficiency of Zap70 causes SCID and preferential loss of CD8 T cells, but curiously, a successful Zap70 inhibitor has yet to be obtained. In contrast, Syk inhibitors have been generated; BIIB057 (Biogen, Cambridge, MA) is being investigated for the treatment of inflammatory diseases, and a second, fostamatinib, is being investigated for the treatment of immune thrombocytopenia and immunoglobulin A (IgA) nephropathy. The recruitment of Zap70/Syk results in activation of another class of PTKs, the Tec family kinases, Rlk and Itk in T cells and Btk in B cells. The importance of this class of kinases is exemplified by the fact that the mutations of *BTK* underlie Bruton agammaglobulinemia a condition characterized by the absence of all B cells (Chapter 34). Ibrutinib is the first BTK inhibitor approved by the FDA in 2014 for the treatment of mantle cell lymphoma and chronic lymphocytic leukemia (CLL).[14] Recent work has identified ibrutinib as an inhibitor of Itk, which suggests it may have value as therapy in autoimmune disease. Antigen receptor activation of phospholipase C (PLC)γ1 appears to require Lck, Zap70, and Tec kinases working in concert. The action of PLCγ1 leads to elevation in intracellular calcium, which in turn activates the phosphatase calcineurin. Calcineurin dephosphorylates and activates nuclear factor of activated T cells (NFAT), which translocates to the nucleus and in cooperation with activator protein-1 (AP-1) transcription factors induces transcription of IL-2 and other key lymphocyte activation genes. A number of potent clinically successful immunosuppressive drugs inhibit calcineurin, including cyclosporine and tacrolimus, drugs that have revolutionized organ transplantation.[15] Despite their success, long-term use of these drugs is limited, as they may cause renal toxicity

CLINICAL PEARLS

Mutations Reveal Key Functions of Kinases in Patients With Primary Immunodeficiencies

- Common γ-chain deficiency, JAK3 deficiency: severe combined immunodeficiency
- ZAP70 deficiency: severe combined immunodeficiency
- TYK2 deficiency: rare cause of hyper-IgE syndrome

Protein Kinase C Family and NF-κB

TCR signaling also leads to the activation of members of the PKC family, which, in turn, activate the transcription factor complex nuclear factor (NF)-κB and the Ras guanyl nucleotide-releasing proteins (RasGRPs). Genetic studies in mice have identified the importance of one member, PKC-θ in TCR signaling. Recent work has identified PKC-θ as an inhibitor of regulatory T cell function.[16] Regulatory T cells (Tregs), unlike conventional effector T cells, act to constrain the immune system. Enhancing Treg numbers or function has been suggested as the treatment of a number of autoimmune diseases.[17] For this reason, preserving or enhancing Treg function through the inhibition of PKC-θ is an attractive strategy. Along with many other receptors, TCR signaling leads to the action of NF-κB family transcription factors, which control the genes involved in cellular activation and resistance to apoptosis.[18] In T cells, PKC-θ is the main isoform responsible for NF-κB activation. The novel PKC inhibitor Sotrastaurin, a potent inhibitor of the PKC-θ, β and α isoforms, is currently undergoing phase II trials for the treatment of diffuse large B-cell lymphoma. Early clinical testing on patients with psoriasis demonstrated that the drug is well tolerated and was able to inhibit T-cell proliferation, IL-2, and IFN-γ secretion. However, despite initial positive trial results, it was not effective in the treatment of psoriasis, ulcerative colitis, or liver transplantation. Downstream of several inflammatory signaling pathways, including PKC, lies the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB).[18] NF-κB has been implicated as a major mediator governing both cancer cell proliferation and survival and governing chronic inflammation. It is held in an inactive state by the binding of the inhibitor of κB (IκB). A cascade of protein kinases that include IκB kinases (IKK) and

IKK kinases (IKKKs), of which PKC and PKB are members, regulate IκB.[18] Several IKK inhibitors have been in development; however, all of them have failed clinical trials.

Lipid Kinases and Downstream Signaling

Kinases are also important in phosphorylating lipids, and these modifications are very relevant in signal transduction through both the TCR and cytokine receptors. In addition to the production of inositol triphosphate by the action of PLCγ1, there is a second pathway of inositol lipid metabolism regulated by the TCR that is a response shared by costimulatory molecules, such as CD28, cytokines, and chemokines. This response is mediated by the class I group of phosphatidyl-inositol 3 kinases (PI3Ks), which is composed of four isoforms (PI3Kα to -δ), which phosphorylate the 3'-OH position of the inositol ring of phosphatidyl-inositol (4,5) bisphosphate (PI(4,5)P_2) to produce PI(3,4,5)P_3.[19] This lipid and its metabolite PI(3,4)P_2 bind to the pleckstrin homology (PH) domains of proteins and either induce localization of the protein to defined areas of the plasma membrane, where activation can occur, or induce conformational changes that allow for allosteric modifications of activity. Targets for D-3 phosphoinositides in T cells include a number of downstream protein serine/threonine kinases and the Rac-1 and RhoA guanine nucleotide exchange proteins. Small-molecule inhibitors of PI3'K, Wortmannin and LY294002, are both potent inhibitors of T-cell activation, although toxicity prevents either from being clinically useful. In contrast to the more widely expressed PI3'Kα and β, PI3'Kγ and -δ are only expressed in hematopoietic tissue and deletion of PI3'Kγ results in defective migration of neutrophils and macrophages to sites of inflammation without other pathology. This limited expression makes PI3'Kγ a potentially useful target, and selective PI3'Kγ inhibitors have shown to be effective in mouse models of collagen-induced arthritis.[20] For similar reasons, PI3'Kδ is another attractive target for which the inhibitor idelalisib was FDA-approved for the treatment of lymphoma.[21] Over 25 other inhibitors of PI3'K are currently being studied in preclinical and clinical trials and include buparlisib, which is in a phase III trial for the treatment of breast cancer.

One PI(3,4,5)P_3-regulated kinase activated by the TCR is protein kinase B (PKB/AKT).[22] T cells stimulated in the presence of the PI3'K inhibitors Wortmannin or LY-294002 fail to activate and proliferate. The ability of cells to take up nutrients and switch on glycolysis is essential for lymphocyte activation; PKB is proposed to be the main effector that mediates the action of PI3'K on these fundamentally important metabolic pathways. There are three PKB isoforms (PKB-α, -β, -γ, or AKT1, -2, -3, respectively), and T cells lacking both *Akt1* and *Akt2* are greatly impaired.[22] Specific inhibitors of PKB are in clinical trials with mixed results; MK-2206 (Merck, Kenilworth, NJ), AZD-5363 (Astra Zeneca, Cambridge, UK), and uprosertib are all in phase II trials for the treatment of several malignancies (see Table 88.3).

In addition to glucose metabolism, the PI3'K-regulated serine/threonine kinase mammalian target of rapamycin (mTOR) regulates protein synthesis in response to cellular nutrient and energy levels.[23] It is activated not only by a number of growth factor receptors but also by cytokines, including IL-2. Many signaling pathways link growth factor receptors with activation of mTOR, including the adenosine monophosphate (AMP)–dependent kinase (AMPK) and phosphatidyl inositol 3' kinase (PI3'K) (see Fig. 88.4). mTOR promotes cell growth by activation of p70 S6K1 and inactivation of 4E-BP1,[23] which are critical for translation of new proteins.

As its name suggests, mTOR is inhibited by the macrolide rapamycin, now licensed as the drug sirolimus for the treatment of graft rejection. Sirolimus does not inhibit mTOR by directly binding to the ATP-binding pocket but acts indirectly, associating with FK506-binding protein 12 (FKBP12). This, in turn, inhibits the kinase complex made up of mTOR, mLST8, and raptor (mTORC1).[23] It was hoped that sirolimus would be a potent anticancer drug, but it has met limited success in this regard. In contrast, it has been successfully used as an immunosuppressant, typically as part of a combination regimen for allograft rejection prophylaxis.[24] In view of the ubiquitous expression of mTOR and its role in protein translation, it is not surprising that sirolimus would be associated with a number of side effects, including hyperlipidemia, hypertriglyceridemia, myelosuppression, and delayed wound healing. There is some evidence of renal toxicity, but this is minor compared with that caused by the calcineurin inhibitors cyclosporine and tacrolimus. Myelosuppression associated with sirolimus is typically dose related and rapidly reversible, even in patients receiving the drug for chronic GvHD.

There are currently three rapamycin derivatives, namely, temsirolimus, everolimus, and AP23573, undergoing clinical trials. Everolimus is licensed for use in the management of heart, liver, and kidney transplantation in conjunction with cyclosporine. It is under investigation for the treatment of arthritis and a number of solid tumors. Temsirolimus is licensed for the treatment of renal cell carcinoma and mantle cell lymphoma. The introduction of novel rapamycin derivatives has been joined by the introduction of pan-mTOR direct inhibitors AZD2014 (AstraZeneca, Cambridge, UK) and CC-223 (Celgene, Summit, NJ), both of which are in phase II trials for the treatment of non-Hodgkin lymphoma and solid tumors.

MAPK Pathways

The MAPK family constitute a complex phospho-relay system of signal transduction, composed of three sequentially activated kinases that are themselves modulated by phosphorylation.[25] Substrates of MAPK pathways include transcription factors, phospholipases, cytoskeletal proteins, and other protein kinases. Three main MAPK cascades have been identified in mammalian cells: the extracellular signal regulated kinase (ERK) cascade, the Jun kinase (JNK) cascade, and the p38 MAPK cascade. All start with a membrane-localized activator followed by three MAPKs that sequentially phosphorylate each other (see Fig. 88.3). The top level of kinases is termed MAPK kinase kinases (MAPKKKs, MKKKs, or Map3Ks). The middle level MAPK kinases (MAPKKs, MKKs, or Map2Ks) phosphorylate a common Thr-Xaa-Tyr motif, where Xaa is any amino acid. The lowest tier consists of the MAPKs that phosphorylate Ser/Thr-Pro motifs. Each pathway terminates in the phosphorylation of substrate proteins.

The ERK Cascade

ERK1 and 2 were identified as kinases that were activated in response to growth factor stimulation, which are mimicked by expression of constitutively active Ras. The link between active Ras and subsequent phosphorylation of the ERKs was made both by the discovery of the MAPK kinase MEK1 and its phosphorylation by the known Ras effector RAF1, now known as a MAPK kinase kinase (M3K). The ERK cascade is ubiquitous in mammalian cells and is generally considered one of the main effector pathways regulated by the GTPase p21ras. Activation of the TCR or the IL-2 receptor is able to trigger ERK signaling in T cells.[25] Two small-molecule inhibitors of this serine/threonine kinase pathway are undergoing clinical trials: the farnesyl inhibitor of Ras tipifarnib, which is in phase III trials for the treatment of acute myeloid leukemia; and the multikinase inhibitor sorafenib, which is FDA approved for the treatment of renal cell carcinoma.[26] Sorafenib is relatively well tolerated despite its ability to inhibit numerous kinases, including the M3K RAF, as well as receptor tyrosine kinases, including platelet-derived growth factor receptor (PDGFR), VEGFR, Kit, and FLT-3. Its role as an immunosuppressant has yet to be explored. There are three RAF isoforms: A-RAF, B-RAF, and C-RAF. A number of cancers are associated with B-RAF mutations resulting in a constitutively active kinase, the best known of which is the V600E mutation. Two kinase inhibitors, vemurafenib and dabrafenib, which are highly active against the B-RAF V600E kinase, are FDA licensed for the treatment of melanoma. Their early use was associated with a partial and short-lived inhibition of the MAPK pathway as C-RAF signaling was preserved, which is often hyperactivated by upstream mutations in Ras signaling or by the presence of B-RAF V600E, which is able to dimerize and activate C-RAF even in the presence of inhibitors.[27] Moreover, clinical trials are ongoing for the treatment of the histiocytosis known as *Erdheim-Chester disease,* for which B-RAF mutations have shown to be present in the vast majority of the case.

The M2K MEK1 and the MAPK ERK1 lie downstream of RAF. Cobimetinib and trametinib are selective MEK inhibitors that are FDA licensed for the treatment of melanoma both as a single agent and in combination with B-RAF V600E inhibitors as they are able to block residual C-RAF signaling.[28] Although all of these agents are seen as anticancer drugs rather than immunosuppressants, it is of note that cobimetinib is currently being assessed in the treatment of Langerhans cell histiocytosis (LCH). LCH is a clonal disorder characterized both by the B-RAF V600E mutation in histiocytes and by the presence of inflammatory lesions that often respond to simple corticosteroid therapy. Selective inhibitors of ERK have been developed: FR180204 has been shown to inhibit the development of collagen-induced arthritis in mice and is being considered as an agent in the treatment of RA. CC90003 (Celgene, Summit, NJ) is currently being assessed in a phase I trial in patients with solid tumors.

The JNK Cascade

Another limb of the MAPK pathway is the JNK pathway. Many inflammatory agents, including lipopolysaccharide (LPS), TNF-α, and IL-1 are able to activate the JNK pathway.[25] In synoviocytes, this results in secretion of proteases implicated in joint destruction seen in RA.[29] A number of small-molecule inhibitors of JNKs have been identified and are currently being investigated in the treatment of inflammation, cancer, and neurological diseases. XG102 (Xigen Ltd., Bedford, UK) is being assessed in phase III trials for the treatment of ocular inflammation and sensorineural hearing loss.

The p38 MAPK Cascade

This cascade was originally identified as part of a drug screen looking for inhibitors of TNF-α–mediated inflammatory responses.[30] TLR-dependent production of IL-1 and TNF-α is p38 MAPK dependent. The success of TNF-α–blocking antibodies in the treatment of RA has led to much interest in the development of p38 MAPK inhibitors. However, although many p38 inhibitors have been reported, their development into therapeutic drugs has been frustrated by either unacceptable toxicity or poor efficacy. Currently, a new generation of p38 MAPK inhibitors are being assessed in phase II trials for the treatment of chronic obstructive pulmonary disease (COPD); losmapimod has recently failed phase II testing because of lack of efficacy, and AZD7624 (AstraZeneca, Cambridge, UK) and acumapimod are still being investigated.

CONCLUSIONS

ON THE HORIZON

- Many kinase inhibitors, initially designed as antitumor agents, have been repurposed as immunosuppressants (*e.g.,* ruxolitinib).
- Further understanding of the pathophysiology of autoimmune disease will lead to the increased use and creation of kinase inhibitors.
- Increasing use of specific kinase inhibitors may improve our understanding of the pathophysiology of autoimmune disease.

Scientific advances in the 1990s have led to the discovery of many novel intracellular signaling pathways that link membrane-bound receptor and cytokine signaling with alteration of gene expression and cellular activation necessary to trigger an immune cell response. Many of these pathways are interlinked to make up a complex array of networks composed of enzymes, adaptor proteins, and transcription factors, all of which are potential targets for drug discovery in the quest to make a therapy that will be able to treat a specific autoimmune disease without an unacceptable degree of immunosuppression. Now more than a decade since the identification of many new targets, the first generation of drugs designed to interfere with specific immune cell signals are being brought to the clinic. The success of the anticancer BCR-Abl inhibitor imatinib and the immunosuppressive mTOR inhibitor sirolimus has placed the protein kinases center stage as targets of future drug discovery. As many of the key steps in the activation of an immune cell are often shared with those that allow a cancer cell to proliferate, many of these agents are being tested as anticancer drugs rather than as immunosuppressants. Despite this, some agents, such as the mTOR inhibitors, originally intended for the treatment of cancer have been far more successful in the field of immunology, and this may continue to be true for future modifiers of cell signaling. Conversely, JAK inhibitors could potentially be used in the treatment of lymphoma. Either way, we are likely to see a large number of novel immunosuppressants appear both serendipitously and intentionally as new protein kinase inhibitors are licensed for a wide range of debilitating illnesses.

MULTIPLE-CHOICE QUESTIONS

1. Specific inhibitors of individual protein kinases are possible because:
   - **A.** Most kinase inhibitors are noncompetitive covalent inhibitors.
   - **B.** Protein kinases can be divided into families of serine, threonine, and tyrosine kinases that are structurally very dissimilar.
   - **C.** The adenosine triphosphate (ATP)–binding pocket of kinases are sufficiently distinct to allow generation of selective inhibitor.
   - **D.** Most kinase inhibitors avoid the structurally similar ATP-binding pocket.
   - **E.** Distinct kinases occupy different parts of the cell and do not interact with each other.

2. The first clinically successful direct tyrosine kinase inhibitor was:
   - **A.** Ruxolitinib
   - **B.** Infliximab
   - **C.** Imatinib
   - **D.** ZAP70
   - **E.** Methotrexate

3. Patients deficient in the following protein kinases suffer from a severe combined immunodeficiency (SCID):
   - **A.** BCR-Abl
   - **B.** JAK3
   - **C.** PTEN
   - **D.** TYK2
   - **E.** BTK

Biological Modifiers of Inflammatory Diseases

W. Winn Chatham

During recent decades, the elucidation of specific inflammatory mediators and identification of lymphocyte lineages that contribute to the pathology underlying chronic inflammatory disorders have identified immunological targets amenable to modification by use of recombinant DNA technologies. The resulting biological modifiers of inflammatory diseases have revolutionized the treatment of rheumatoid arthritis (RA), inflammatory bowel disease (IBD), psoriasis, spondyloarthropathies, antineutrophil cytoplasmic antibody (ANCA)–associated vasculitis syndromes, systemic lupus erythematosus (SLE), and other autoimmune diseases, as well as allergic disorders. These targeted therapies, although costly, offer individuals affected by these disorders options for better disease control and less of the morbidity associated with greater exposure to broader immune suppression and/or corticosteroid use. This chapter summarizes the biological modifiers of inflammatory diseases that are currently available or in development classed by mechanism of activity and molecular nature.

IMMUNOMODULATORY CYTOKINES

Recombinant Interleukin-2 (Aldesleukin)

First identified as a T-cell growth factor, recombinant interleukin-2 (rIL-2) has potent immunomodulatory and antitumor activity, promoting the proliferation, differentiation, and recruitment of T cells, B cells, and natural killer (NK) cells (Table 89.1). rIL-2 has primarily been used therapeutically in patients with advanced melanoma and in patients with advanced renal cell carcinoma. IL-2 is a potent inducer of proinflammatory T-cell cytokines, such as IL-1, tumor necrosis factor-α (TNF-α), and interferon-γ (IFN-γ), all of which likely play a major role in dose-related IL-2 toxicity, which may include hypotension, cardiac arrhythmias, increased capillary permeability with pulmonary edema, fever, and rarely death. The use of aldesleukin in patients with cancer has been increasingly supplanted by more targeted immune-enhancing "checkpoint" therapies targeting T-cell death receptors (programmed death 1 [PD-1]) and cytotoxic T lymphocyte antigen-4 (CTLA-4), which have comparable antitumor effects with much less acute toxicity.

More recently, the administration of low-dose rIL-2 has been shown to promote preferential growth and proliferation of regulatory T cells (Tregs) without significantly affecting the release of inflammatory mediators by CD4 T cells.[1] Such low-dose regimens of rIL-2 have been used with success in suppressing manifestations of graft-versus-host disease (GvHD) and may also favorably impact the course of type 1 diabetes.[1] The use of rIL-2 and/or other cytokine therapies promoting enhanced Treg differentiation and proliferation may therefore provide novel interventions for managing a variety of inflammatory disorders associated with autoimmunity, including SLE.[2]

KEY CONCEPTS

Interferons: Therapeutic Potential

- Interferon-α (IFN-α) has been used with success to enhance resolution of chronic viruses, notably hepatitis C virus (HCV); newer antivirals are supplanting the need for IFN therapy in HCV.
- IFN-β has immunomodulatory effects that are of benefit in the treatment of certain subsets of patients with multiple sclerosis (MS).
- Type 1 IFNs (including IFN-α and IFN-β) may unmask or trigger flares of autoimmune disease, most notably systemic lupus erythematosus (SLE).
- IFN-γ may be of some benefit in the management of patients with chronic granulomatous disease (CGD) not responding to antifungal and antibacterial prophylactic regimens.

Interferons

IFNs, released primarily by T lymphocytes as well as dendritic cells (DCs) in the context of stimulation of Toll-like receptors (TLRs) have a wide array of immunomodulatory effects that include upregulation of genes governing angiogenesis, cell differentiation, expression of human leukocyte antigen (HLA) molecules, and production of inflammatory cytokines. IFN-α and IFN-β bind to the same cell surface receptor (IFN-1R) and are designated type-1 IFNs, whereas IFN-γ binds to a different receptor (IFN-2R) and is designated as a type 2 IFN. Recombinant preparations of all three IFNs have been used for the management of inflammatory disorders associated with chronic viral infection, primary immunodeficiency (PID), or select autoimmune disorders (most notably multiple sclerosis [MS]). Although there are immunomodulatory attributes that render IFNs useful in certain circumstances, constitutional symptoms and upregulation of a wide variety of genes that promote inflammation frequently limit the use of both type 1 and type 2 IFNs.

Interferon-α

Recombinant IFN-α2b (rIFN-α2b) has most commonly been used in combination with ribavirin for treatment of hepatitis C, including hepatitis C virus (HCV)–associated cryoglobulin syndromes.[3] Other disorders linked to viral infections, including lymphomatoid granulomatosis (caused by Epstein-Barr virus [EBV]) and polyarteritis nodosa (caused by hepatitis B virus [HBV]), have been successfully treated with regimens incorporating IFN-α2b as part of the treatment regimen.[4] Refractory retinal

TABLE 89.1 Recombinant Immunomodulatory Cytokines

Molecule	Construct	Half-Life	Dosing
aldesleukin	rIL-2	1.5 hours	0.3–3 × 10^6 IU/m^2 subcutaneously (SC) daily
IFN-α2b	rIFN-α2b	1.7 hours	3–10 × 10^6 IU 3x/week
IFN-α2b pegylated	rIFN-α2b pegylated	17 hours	50–150 μg/week
IFN-β1a	rIFN-β1a	69 hours	8.8–44 μg SC 3x/week
INF-β1b	rIFN-β1b	0.2–4.3 hours	2–8 × 10^6 IU every other day
IFN-γ	rIFN-γ	6 hours	50 μg (1 × 10^6 IU)/m2 SC 3x/week

vasculitis in the context of Behçet disease, severe flare-ups of familial Mediterranean fever not responding to treatment with colchicine, and eosinophilic granulomatosis with polyangiitis (EGPA) have also been reported to respond favorably to treatment with rIFN-α2b.[5,6]

Common side effects of rIFN-α2b include flu-like syndrome, fatigue, anorexia, nausea, weight loss, hair loss, emotional lability and depression, cytopenias, and induction of autoantibodies with enhancement of autoimmune disease. Because of these consequences of treatment, the inconstant efficacy against certain HCV genotypes, and the availability of more highly effective antiviral agents targeting HCV replication, use of rIFN-α2b in the treatment of HCV has decreased.

Interferon-β

Recombinant IFN-β1a or IFN-β1b (rIFN-β) has been shown to decrease relapse rates, disease severity, and central nervous system (CNS) magnetic resonance imaging (MRI) lesions in patients with relapsing MS. However, there are conflicting data with regard to the efficacy of IFN-β1a or IFN-β1b preparations for patients with secondary progressive variants of MS.[7] Immunomodulatory effects attributed to the beneficial impact of IFN-β1b on MS include enhancement of suppressor T-cell activity, reduction of proinflammatory cytokines, downregulation of antigen presentation, and reduced trafficking of lymphocytes into the CNS.[7] Side effects observed during treatment with both rIFN-β preparations include injection site reactions as well as most of the effects observed during treatment with rIFN-α2b. Reported autoimmune complications include SLE-related complications as well as features often associated with SLE, including immune complex glomerulonephritis, cutaneous vasculitis, and panniculitis.[8]

Interferon-γ

Recombinant IFN-γ (rIFN-γ) is effective in decreasing the frequency and severity of infections in patients with chronic granulomatous disease, an inherited disorder associated with any number of genetic defects that impair assembly of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and production of superoxide anion metabolites in neutrophils.[9] In permissive X-linked variants of chronic granulomatous disease (CGD), treatment with rIFN-γ appears to increase superoxide production. However, infection outcomes in murine models of CGD void of any capability of superoxide generation are still improved, so it is unclear whether the noted favorable impact on infection frequency and severity observed with rIFN-γ use is attributable to its effects on superoxide production.[10]

Fever, myalgias, rash, fatigue, and diarrhea are the most common adverse events associated with IFN-γ treatment. During intercurrent infections, treatment with rIFN-γ often enhances infection-related constitutional symptoms, potentially obscuring responses to antimicrobial therapy. With greater adherence to antimicrobial prophylactic regimens incorporating combination therapy with itraconazole and trimethoprim-sulfamethoxazole (TMP-SMX), the added benefit of treatment with rIFN-γ in patients with CGD may be marginal.

KEY CONCEPTS

Tumor Necrosis Factor-α (GR) Inhibitors

- Tumor necrosis factor (TNF)-α inhibitor treatment significantly improves patient symptoms and function and inhibits structural damage in patients with rheumatoid arthritis (RA).
- TNF-α inhibitors are very effective in suppressing skin lesions caused by psoriasis as well as entheseal inflammation in patients with seronegative spondyloarthropathies; they do not appear to have any inhibitory effects on the development of bony ankyloses.
- Vigilance for underlying fungal disease or mycobacterial disease is prudent prior to commencing with and during treatment courses with TNF-α inhibitors.
- TNF-α inhibitors may trigger or exacerbate certain autoimmune syndromes and should be used with caution or avoided in patients with autoantibody-associated immune disorders, such as systemic lupus erythematosus (SLE).

INHIBITORS OF INFLAMMATORY CYTOKINES

Tumor Necrosis Factor-α Inhibitors

TNF-α is a significant mediator of inflammation associated with psoriasis, RA, spondyloarthropathies, and chronic inflammatory bowel diseases (IBDs; Crohn disease and ulcerative colitis [UC]). TNF-α promotes the ingress of immunocompetent cells at sites of inflammation through activation of the vascular endothelium and upregulation of adhesion molecules. TNF-α also stimulates synthesis of other pro-inflammatory cytokines (IL-1β, IL-6, granulocyte macrophage–colony-stimulating factor [GM-CSF]), chemokines (IL-8), and inflammatory eicosanoids (prostaglandin E$_1$ [PGE$_1$], leukotriene B$_4$ [LTB$_4$]).[11] In RA, TNF-α stimulates macrophages and monocyte-derived osteoclasts to release mediators destructive to bone and cartilage, including matrix metalloproteinases (MMPs), such as collagenase and stromelysin. These noted effects of TNF-α have, therefore, prompted the development of both soluble receptor and monoclonal reagent strategies to inhibit the effects of TNF-α in disorders, in which it appears to have a significant role in promoting inflammation and tissue injury (Table 89.2).

Etanercept is a recombinant soluble p75 TNF receptor (TNFR; CD120b)-IgG Fc fusion protein that binds soluble TNF-α as well as lymphotoxin-β. The avidity of the p75 TNFR for soluble TNF-α is comparable with that of the p55 TNFR and therefore effectively decreases net TNF signaling through either of these receptors. The clinical impact of binding lymphotoxin-β is not entirely known, but recent work elucidating the role of lymphotoxin-β in maintaining the physiological regulatory function of macrophages around lymphoid germinal centers suggests that inhibition of this cytokine may enhance the delivery of apoptotic body–derived self-antigens to germinal centers, a

TABLE 89.2 Recombinant Inhibitors of Pro-Inflammatory Cytokines

Molecule	Construct	Half-Life	Dosing (Maintenance)
Etanercept	sTNFR:Fc	3–4 days	50 mg subcutaneously (SC) once a week or 25 mg SC 2x/week
Infliximab	aTNF-α (chimeric IgG1κ)	7–12 days	3–10 mg/kg intravenously (IV) q4–8 weeks
Adalimumab	aTNF-α (human IgG1κ)	10–20 days	10–40 mg SC q1–2 weeks
Certolizumab	aTNF-α (humanized Fab')-PEG	14 days	200-400 mg SC q2–4 weeks
Golimumab	aTNF-α (human IgG1κ)	14 days	50-100 mg SC every 4 weeks 2 mg/kg IV every 8 weeks
Anakinra	sIL-1Ra	4–6 hours	1–8 mg/kg SC daily (max 200 mg/day)
Rilonacept	IL-1R1:Fc(IgG1):IL-1RAcP	8–9 days	2.2 mg/kg (max 160 mg) SC per week
Canakinumab	aIL-1β (human IgG1κ)	26 days	2–8 mg/kg SC (max 600 mg) SC every 8 weeks
Tocilizumab	aIL-6R (humanized IgG1κ)	13 days	4-12 mg/kg (max 800 mg) IV every 2–4 weeks 160 mg SC every 1–2 weeks
Ustekinumab	aIL-12/23 p40 (human IgG1κ)	15–32 days	0.75 mg/kg (pediatric) or 45–90 mg SC every 12 weeks
Secukinumab	aIL-17A (human IgG1κ)	22–31 days	150-300 mg SC every 4 weeks
Ixekizumab	aIL-17A (humanized IgG4κ)	13 days	80 mg SC every 2–4 weeks

consideration of potential clinical relevance in patients at risk for SLE or related autoimmune syndromes (see below).

Infliximab, adalimumab, and *golimumab* are monoclonal antibody (mAb) reagents with comparable avidity for both soluble and cell-bound TNF-α but differ with regard to the derivation of the antigen-binding sequence and half-life. Infliximab is a chimeric antibody with a murine-derived variable-region TNF-binding domain. Adalimumab and golimumab are both human sequence–derived mAb reagents. *Certolizumab pegol* is a construct consisting of recombinant human sequence–derived F(ab)' anti–TNF-α covalently liked to 40-kilodalton (kDa) polyethylene glycol. The pegylated construct enhances the half-life of the reagent, and absence of the Fc- and complement-binding domains renders certolizumab less likely to engender local injection site reactions and precludes placental crossing of certolizumab into the fetal circulation when administered to pregnant women.

In cytokine profile studies of joint tissues and synovial fluids derived from patients with RA, TNF-α is consistently among the highest expressed inflammatory cytokines.[11] All five TNF-α inhibitors have been shown to decrease the signs and symptoms of disease activity and to inhibit the progression of structural damage in RA, with greatest benefits and probability of disease remission seen among patients with early RA. Inhibition of radiographic progression of disease, as measured by joint space narrowing and osseous erosions at joint margins, can be dissociated from clinical efficacy as measured by composite scoring measures, such as the American College of Rheumatology 20%/50%/70% improvement criteria or the Disease Activity Score (DAS)-28.[12]

TNF-α levels are also notably increased in biopsy samples of skin and synovial tissues from patients with psoriasis and psoriatic arthritis, and the TNF-α inhibitors have been shown to be highly effective in suppressing manifestations of plaque psoriasis as well as articular disease in psoriatic arthritis.[13,14] Improvements in joint symptoms (axial and peripheral) and uveitis manifestations are observed in patients with other spondyloarthropathies, including ankylosing spondylitis, during treatment with TNF-α inhibitors; however, use of these agents has not been shown to delay fusion of axial joints in patients with spondylitis. Insights from rodent models and the known inhibitory effect of TNF-α on Smad pathway–mediated bone formation by osteoblasts suggest that TNF inhibition may, in fact, promote ossification at sights of inflammation and increased bone turnover.[15]

mAb inhibitors of TNF-α as well as certolizumab (but not etanercept) have been shown beneficial in the management of intestinal inflammation in patients with Crohn disease or UC and are approved for treatment of these disorders.[16] Pyoderma syndromes and the oral and genital lesions of Behçet disease are reported to respond favorably to TNF-α inhibition therapy.[17,18]

Although very well tolerated as a class, TNF-α inhibitors may impair innate host defenses, resulting in delay of resolution of intercurrent infections. TNF-α inhibitors are associated with reactivation of tuberculosis and fungal infections, including histoplasmosis and coccidioidomycosis, and viral infections such as hepatitis B.[19,20] In all circumstances of intercurrent infection, the standard recommendation is for treatment with TNF-α inhibitors to be withheld until the infection has resolved. No complications have been reported regarding their use in patients with intercurrent hepatitis C infection or in patients with human immunodeficiency virus (HIV) infection that is well controlled with highly active antiretroviral therapy (HAART).

In the context of its role in promoting cell apoptosis, TNF-α constitutes a component of the host defense against tumor cell survival and growth. As such, the incidence and prevalence of cancer in populations treated with TNF-α inhibitors has been emphasized in pharmacovigilance programs surrounding the use of this class of therapeutic agents. Lymphoma has been reported in patients treated with TNF-α inhibitors, with most reported cases occurring in the context of treatment for RA. However, the relative risk for lymphoma in patients with RA in the pre–biologicals era approximates 3.0, and the prevalence of lymphoma in patients with RA exposed to TNF-α inhibitors has not been shown to exceed the otherwise expected prevalence among patients with RA. Among patients with RA, IBD, or psoriasis, the risk of cancer has not been shown to be increased in the context of treatment with TNF-α inhibitors.[21] Although it is often recommended that TNF-α inhibitor therapy be discontinued in the setting of a newly diagnosed cancer and that initiation of such therapy be avoided in patients with known malignancy, there are no clinical data to confirm whether continued treatment with TNF-α inhibitors impairs therapeutic response to cancer therapy.

The role of TNF-α inhibition in facilitating apoptosis is also of relevance with regard to the development or potentiation of autoimmunity. Although rare, the development of psoriasiform skin eruptions, demyelinating syndromes, and drug-induced SLE are well documented occurrences in patients treated with TNF-α inhibitors.[22-24]All of the anti–TNF-α reagents may attenuate TNF-α–mediated apoptosis of autoreactive T cells. Infliximab, adalimumab, and golimumab may induce the release of apoptotic products in the context of antibody-dependent cellular cytotoxicity (ADCC) of cells bearing surface TNF-α, potentially driving production of antibodies to nucleoproteins.[25] Binding of lymphotoxin-β by etanercept may alter the clearance of apoptotic products by germinal center adjacent follicular DCs and macrophages.[26] Given these collective considerations, it is generally recommended that TNF-α inhibitors be discontinued in patients who develop autoimmune complications during treatment with this class of biological therapy. Moreover, anti–TNF-α therapy is not recommended for patients with established SLE or other overlap syndromes with lupus-like features associated with autoantibody production.

Interleukin-1β Inhibitors

IL-1β is synthesized as an inactive precursor, with activation of IL-1β occurring following engagement of nucleotide-binding oligomerization domain (NOD)–like receptors (NLRs) by a variety of exogenous or endogenous danger signals, which then trigger formation of molecular platforms (NLR family domain containing protein 3 [NALP] inflammasomes) that facilitate cleavage of the IL-1β precursor by IL-1–converting enzyme (ICE).[27] IL-1β stimulates proliferation of lymphocytes, upregulates the expression of adhesion molecules, and triggers the release of a variety of inflammatory mediators from leukocytes, including chemotactic factors, prostaglandins, proteases, and procoagulants. In patients with RA, IL-1β triggers the release of proteases from phagocytic cells and macrophages that are destructive to bone and cartilage. Inflammasome activation has also been shown to mediate acute flare-ups of arthritis in patients with gout or calcium pyrophosphate deposition. Dysregulation of NLRP3 as a result of gain-of-function mutations in inflammasome-related genes has been implicated in the pathogenesis of familial cryopyrin-associated periodic syndromes (CAPS, cryopyrinopathies), familial Mediterranean fever (FMF), and the pyogenic arthritis, pyoderma gangrenosum, and acne syndrome (PAPA). Increased expression and levels of IL-1β are also noted during flare-ups of inflammation in patients with adult-onset Still disease (AoSD), systemic-onset juvenile idiopathic arthritis (soJIA), and macrophage activation syndromes (MAS) associated with these and other autoimmune or infectious disorders.[27] The naturally occurring IL-1 receptor antagonist (IL-1Ra) prevents the binding of IL-1β and IL-1α to the IL-1 receptor (IL-1R), but tissue levels of IL-1Ra in in the above disorders may be insufficient to counteract the effects of IL-1β.

KEY CONCEPTS

Interleukin Inhibitors

- Interleukin (IL)-1β inhibitors are very effective in the treatment of disorders associated with constitutional or secondary activation of the IL-1 inflammasome, including cryopyrin syndromes, familial Mediterranean fever flare-ups, and flare-ups of crystal induced arthropathy (gout and calcium pyrophosphate dihydrate [CPPD] crystal deposition disease/pseudogout).
- Use of IL-1β inhibitors with a short half-life may be of benefit in managing severe flare-ups of inflammation associated with macrophage activation, such as systemic-onset juvenile idiopathic arthritis (soJIA), adult-onset Still disease, and severe sepsis syndromes.
- IL-6 signaling is complex in the context of signaling that can occur through cell membrane bound IL-6R, which mediates primarily IL-6 homeostatic effects, or through many other cell receptors that engage IL-6/sIL-6R complexes (trans-signaling), which mediate IL-6 inflammatory effects.
- Inhibition of IL-6 binding to IL-6R mediated by monoclonal antibody (mAb) reagents, such as tocilizumab, is very effective in suppressing clinical manifestations of rheumatoid arthritis (RA).

Anakinra is a nonglycosylated recombinant IL-1 receptor antagonist (rIL-1Ra) that differs from the endogenous IL-1Ra by a single amino acid addition at the amino terminus. Administered subcutaneously at daily (or for some indications more frequent) intervals because of its very short serum half-life, anakinra functions as a competitive inhibitor of IL-1α and IL-1β binding to IL-1 receptors.

Anakinra, presently approved for the treatment of RA, inhibits joint erosions. However, compared with the clinical responses observed with use of TNF inhibitors and IL-6 inhibitors (tocilizumab) with regard to tender and swollen joints, such responses with anakinra are much more modest. Given these observations with biologicals that require much less frequent dosing, anakinra is used infrequently in the treatment of RA. With the increased understanding of the role of IL-1 inflammasome activation in crystal-induced arthropathies, such as gout and systemic inflammatory disorders, such as soJIA and AoSD, anakinra has been gaining renewed interest as a therapeutic option in the treatment of these disorders. Case reports support use of anakinra in managing acute flare-ups of gout or flare-ups of calcium pyrophosphate–associated pseudogout when the use of corticosteroids or nonsteroidal antiinflammatory drugs (NSAIDs) is not favored because of comorbid conditions, such as uncompensated heart failure or diabetes with significant renal impairment.[28] Prompt resolution of inflammatory markers and clinical manifestations have been reported in patients with severe flare-ups of AoSD and soJIA treated with anakinra, including those associated with MAS.[29,30] The relatively short half-life of anakinra may render its use feasible when short-term blockade of IL-1 may be of benefit in managing severe flare-ups of IL-1–driven inflammation when there is a concern for intercurrent infection. The potential utility of anakinra in this context is supported by a recent study reexamining the outcomes from a previous sepsis trial, where survival was shown to have improved in patients with clinical features of MAS who were randomized to anakinra treatment.[31]

Rilonacept (also referred to as *IL-1-Trap*) is a recombinant fusion protein that comprises the extracellular domain of the IL-1 accessory protein and IL-1 receptor type 1 attached to the Fc portion of immunoglobulin G1 (IgG1). Rilonacept binds to IL-1α and IL-1β with high affinity and is approved for the treatment of CAPS. Similar to anakinra, rilonacept is dosed subcutaneously, albeit at weekly intervals because of its longer half-life. It is generally well tolerated, with injection site reactions being the most common adverse events.

Canakinumab is a human genome sequence–derived mAb with specificity for IL-1β that also binds to IL-1α. Approved for the treatment of CAPS as well as soJIA, canakinumab has the longest half-life of the currently approved therapies that target IL-1. In a randomized clinical trial comparing the use of canakinumab with parenteral triamcinolone administration for acute gout flare-ups, canakinumab was shown to have greater reductions in joint pain and swelling, decreased needs for rescue medications, and a greater time to subsequent flare-ups.[32] However, given that the observed rates of serious infections were twice as high in the canakinumab arm, a half-life that well exceeds the duration of typical flare-ups, and the questionable cost-effectiveness of using an intervention 5000 times the cost of current therapies that are, by and large, effective for managing acute gout, the use of canakinumab has not found favor in treatment paradigms for managing gout.

Interleukin-6 Inhibitors

IL-6 mediates the activation of macrophages and osteoclasts, terminal proliferation and differentiation of B cells, differentiation of T-helper 17 (Th17) cells, and production of liver acute-phase proteins.[33] However, IL-6 also governs homeostatic processes, including granulopoiesis, enteric epithelial proliferation, and antiinflammatory responses involved in resolution of inflammation, including production of the soluble TNFR p55 and the IL-1Ra.[34]

The biology of IL-6 signaling is complex in that signaling may occur directly through the cell membrane–bound IL-6 receptor (IL-6R)/gp130 protein complex (classic signaling) or through binding of IL-6 to soluble IL-6R (sIL-6R) with the resulting heterodimer and then ligating a variety of other gp130-containing membrane receptors (trans-signaling) that mediate signaling from cytokines other than IL-6. IL-6R is expressed primarily on leukocytes, hepatocytes, and megakaryocytes, whereas gp130-containing receptor complexes are expressed in almost all organs, including the heart, kidneys, spleen, liver, lungs, placenta, and brain. In murine models of inflammation employing sgp130:Fc constructs that selectively bind and neutralize IL-6/sIL-6R, trans-signaling appears to mediate many of the observed inflammatory consequences of the upregulation of IL-6, whereas classic signaling through membrane IL-6R mediates homeostatic processes, such as granulopoiesis, thrombopoiesis, and epithelial cell proliferation.[35] With greater understanding of the different IL-6 signaling pathways in humans, implementation of therapeutic strategies targeting IL-6 will require consideration of the impact of blocking classic membrane-bound IL-6R signaling and IL-6/sIL-6R trans-signaling.

Tocilizumab is a humanized mAb with specificity for the human IL-6 receptor. Tocilizumab blocks the binding of IL-6 to IL-6R, inhibiting both classic signaling by IL-6 through membrane IL-6R and formation of IL-6/sIL-6R heterodimer ligands that engender trans-signaling.[36] Treatment with tocilizumab improves tender and swollen joint counts and slows the development of joint erosions in patients with RA.[37] Treatment with tocilizumab is also reported to be of benefit in patients with soJIA, AoSD, and Castleman disease.[38,39]

Presumably related to the role of IL-6 in promoting granulopoiesis, neutropenia may be observed in some patients following treatment with tocilizumab, but this is uncommon. Thrombocytopenia and elevated serum aminotransferase levels have also been observed on rare occasions. A predictable mild increase in serum lipid levels is observed following the initiation of treatment with tocilizumab; the clinical significance of this remains indeterminate, but monitoring of lipid levels is recommended. Reactivation of tuberculosis and invasive fungal infections can occur, and rare instances of gastric and intestinal rupture have been reported in patients treated with tocilizumab. These observed effects on hematopoiesis and loss of intestinal integrity reflect the potential downsides of complete blockade of IL-6–mediated functions that is inherent in the use of mAb reagents that block the interaction of IL-6 with the IL-6R and emphasize the potential advantages of more selective IL-6 pathway inhibition (see below, sgp130:Fc).

On the Horizon: Other Anti–IL-6R and Anti–IL-6 mAbs and Sgp130:Fc Reagents

Several other recombinant mAb-based reagents that inhibit both classic and trans-signaling mediated by IL-6 are in advanced clinical development. *Sarilumab* (human anti–IL-6R) has been shown in phase III trials to have demonstrated efficacy in the treatment of RA. *Vobarilizumab* is a nanobody construct consisting of an IL-6R–specific non-Fc IgG heavy chain covalently linked to serum albumin that blocks binding of IL-6 to both membrane-bound and soluble IL-6R, currently being evaluated for treatment of SLE. *Sirukumab* and *Olokizumab* are humanized anti–IL-6 constructs that have also been shown in phase II trials to have efficacy in RA. *Clazakizumab* (humanized anti–IL-6) has shown promising results for the treatment of RA as well as musculoskeletal symptoms in patients with psoriatic arthritis. By virtue of engineered aglycosylation, clazakizumab has a longer half-life than other mAb reagents targeting IL-6 or IL-6R, thereby requiring less frequent dosing; however, with higher dose ranges, the frequency of serious adverse events and infections appears to be increased.

Of potentially greater interest is the development of soluble gp130 covalently linked to immunoglobulin Fc (*sgp130:Fc*), a construct with specificity for the IL-6/sIL-6R heterodimer that mediates IL-6 trans-signaling. Selective inhibition of the trans-signaling pathway linked to inflammatory responses may be superior to complete IL-6 blockade because important physiological functions of IL-6 mediated through membrane-bound IL-6R are left intact. These differences have been emphasized in a murine model of peritonitis, where selective inhibition of IL-6 trans-signaling by sgp130:Fc as opposed to complete blockade of IL-6 signaling by anti–IL-6 mAb was shown to significantly improve survival and completely prevent intestinal epithelial cell apoptosis.[40] Observations in murine models of tuberculosis have further confirmed the absence of any impaired response to disease resolution in the setting of either sgp130:Fc transfection or administration of sgp130:Fc constructs.[41]

Interleukin-12/-23 Inhibitors

IL-12 and IL-23 are heterodimeric molecules that share a common p40 subunit but have different immunological effects on T-cell lineage development. IL-12 comprises p35/p40 subunits and promotes the development and maturation of Th1 lineage T cells, a significant source of IFN-γ. IL-23 comprises p19/p40 subunits and promotes the maturation and survival of Th17 lineage T cells. Initial strategies targeting the shared p40 subunit of IL-12/IL-23 in murine models of autoimmune inflammation yielded promising results and prompted human trials in psoriasis, RA, and IBD. Subsequent comparative IL12/IL-23 p40, IL-12 p35, and IL-23 p19 knock-out studies in the murine models suggest that the observed ameliorative effects of anti-p40 on inflammation in the models studied were by virtue of IL-23 inhibition.[42] As a consequence, selectively targeting IL-23 and IL-17 (the primary effector cytokine of Th17 cells) has evolved as a strategy to treat autoimmune inflammation.

Ustekinumab is a humanized IgG1κ mAb with specificity for the p40 subunit component of IL-12 and IL-23. Approved for the treatment of psoriasis and psoriatic arthritis, ustekinumab significantly improves skin lesions as measured by the psoriasis area and severity index (PASI), and has been shown to decrease both peripheral and axial joint/enthesis manifestations in psoriatic arthritis.[43] Although not yet approved for patients with IBD, significant improvements in Crohn disease activity have been reported in patients treated with ustekinumab, most notably among patients who failed to respond adequately to anti–TNF-α therapies.[44]

In the reported clinical trials for psoriasis, there were no increased occurrences of serious infections or other serious adverse events in the ustekinumab-treatment arms relative to the placebo-treatment arms. Higher than expected rates of infection or malignancy have also not been observed in other controlled studies of ustekinumab in spondylitis or IBD. Nonetheless, vigilance for mycobacterial, fungal, and *Salmonella* infections is recommended, given the role of IL-12 and IL-23 in host defense against these pathogens.

On the Horizon: IL-23 Specific Inhibitors

Tildrakizumab and *Guselkumab* are fully human IL-23 p19–specific mAbs currently being evaluated in clinical trials for treatment of psoriasis.

Interleukin-17 Inhibitors

IL-17 is a cytokine elaborated primarily by the Th17 lineage of effector T cells, which differentiate from Foxp3$^-$CD4$^+$ thymocytes under the influence of IL-6 and transforming growth factor-β (TGF-β) and proliferate/survive under the influence of IL-23. Th17 cells are prevalent in the inflammatory lesions of a variety of inflammatory disorders, including RA, IBD, psoriasis, and spondyloarthropathies. IL-17 is produced by a variety of innate immune cells, including neutrophils, mast cells, keratinocytes, macrophages, NK cells, NKT cells, and innate lymphoid cells (ILCs; LLC/LTi), triggering the induction and release of IL-6, TNF-α, CCL2, CCL3, MMPs from macrophages, inducing activation of osteoclasts at sites of bone resorption, and promoting the proliferation, maturation, and chemotaxis of neutrophils.[45,46] As such, IL-17 is important both in the initial innate host defense to infection and also inflammation driven by acquired immune responses. Given the multitude of effects mediated by IL-17 in perpetuating inflammation in a number of autoimmune disorders, mAb reagent–based strategies have been developed targeting IL-17 and its receptor (Table 89.2).

KEY CONCEPTS

Approaches to IL-17 Inhibition

- Selective inhibition of pathways promoting differentiation and activation products of T-helper 17 (Th17) cells is of significant benefit in the treatment of psoriasis and the seronegative spondyloarthropathies.
- Selective inhibition of interleukin (IL)-17A appears to be of marginal benefit in the treatment of inflammatory bowel disease (IBD), whereas inhibition of both IL-12 and IL-23 by targeting their shared p40 subunit appears to be of benefit in both psoriasis and IBD.

Secukinumab

Secukinumab is a fully human IgG1 mAb that selectively binds to and neutralizes IL-17A. In clinical trials, secukinumab has been shown to significantly decrease the activity of skin lesions in patients with psoriasis, decrease tender and swollen joints in patients with psoriatic arthritis, and decrease axial pain and limitation in patients with ankylosing spondylitis.[47,48] Clinical responses to secukinumab in patients with RA have been less robust. Despite the apparent role of Th17 cells in patients with IBD, no significant improvement and was observed in patients with Crohn disease, and in some of these patients, the disease worsened during treatment with secukinumab.[49]

In clinical trials of secukinumab in patients with psoriasis, rates of infection are increased over that observed in patients randomized to placebo, but not in excess of the infection rates noted with anti-TNF therapy. Increased rates of serious infection have not been observed in relatively short-term RA clinical trials with secukinumab. However, given the pivotal role of Th17 in host responses to chronic and acute infections by bacteria, parasites, and fungi, it is possible that alterations in the containment of microbial pathogens in the enteric mucosa may account for the failure of targeting IL-17 in IBD.

Ixekizumab

Ixekizumab is a humanized IgG4 mAb targeting IL-17A that has been shown to be effective and approved for the treatment of plaque psoriasis. Similar to what has been observed in clinical trials with secukinumab, rates of infection are slightly increased in patients treated with ixekizumab versus placebo, but in short-term studies conducted so far, the rate of serious infections has not been observed to be increased relative to that observed in patients randomized to placebo or a comparative arm of patients randomized to anti-TNF treatment with etanercept.[50]

On the Horizon: Il17 Receptor Antagonists

Brodalumab is an anti–IL-17Ra monoclonal antibody. Data from two identically designed phase III randomized trials support the efficacy of brodalumab for treatment of moderate to severe plaque psoriasis. Efficacy with regard to clearing skin lesions was noted to be significantly greater than that observed in a comparator group receiving ustekinumab, but *Candida* infections and neutropenia were more frequent in the brodalumab groups than in the ustekinumab and placebo groups.[51]

Other Immunomodulatory Cytokines and Cytokine Inhibitors

On the Horizon: Inhibitors of the Type 1 Interferon Pathway

With increasing recognition of the role of type 1 IFNs in the immunopathogenesis of SLE, strategies to target IFN-α for treatment of SLE have emerged. Initial trials with mAb reagents, such as *rontalizumab* or *sifalimumab* with specificity to one or more of the known IFN-α subtypes (14 known presently), have yielded modest results, emphasizing the complexity of the IFN system in SLE. This strategy is further complicated by the recognition that autoantibodies to IFN-α are often prevalent in SLE sera. The alternative approach of targeting the type 1 IFN receptor (IFN-1R) in a recent phase II trial with *anifrolumab* has yielded more encouraging results.[52] Targeting the IFN-1R may also prove efficacious in other autoimmune disorders, such as SLE and Sjögren syndrome, which are associated with an enhanced type 1 IFN signature. Other approaches targeting the production of type 1 IFNs currently under investigation include the use of mAb reagents to deplete plasmacytoid dendritic cells (pDCs), perceived to be the major source of IFN-1 in SLE.

In the relatively short-term clinical trials conducted thus far with antibodies targeting IFN-α or IFN-1R, increased susceptibility to viral pathogens has not been observed. Whether depleting pDCs, blocking one or more TLRs linked to upregulation of type 1 IFNs, blocking IFN-1R, or using mAb reagents capable of neutralizing multiple IFN subtypes critically important in SLE and related autoimmune disorders will prove efficacious but not at the expense of susceptibility to viral disease remains to be determined in phase III trials.

On the Horizon: Recombinant Promoters of Treg Function

IL-27 may modulate autoimmune inflammation via promotion of Treg lineage and function; it often opposes the action of IL-6 and is the only member of the gp130-related cytokine family to predominantly signal via the latent transcription factor signal transducer and activator of transcription 1 (STAT1) instead of STAT3.[53] In this context, IL-27 acts as a negative regulator of Th17 commitment, whereas the p28 subunit of IL-27 antagonizes IL-6–STAT3-mediated T-cell responses. Treg function may also be enhanced by recombinant *IL-35.*[54]

Complement Pathway Inhibitors

In addition to opsonization of microbial pathogens and products of apoptosis, products of complement activation play a significant role in recruitment and activation of phagocytic cells (C3a, C5a), cell membrane damage (C5b-9), and have potent procoagulant activity (C5a, C5b-9) (Table 89.3). Congenital deficiency of C3 or functional C3 impairment is typically associated with severe, if not fatal, clinical phenotypes, rendering C3 or its cleavage products unattractive targets for immunomodulation. However, inhibition of C5 appears to be well tolerated and may have beneficial effects on disorders in which enhanced cleavage of C5 contributes to disease manifestations (Table 89.3).

KEY CONCEPTS

Inhibitors of Complement Activation and Cell Migration

- Inhibition by eculizumab of C5 cleavage to its active products and resulting assembly of the membrane attack complex is of significant benefit to patients who have complement-mediated thrombotic microangiopathy syndromes occurring with atypical hemolytic–uremic syndrome, catastrophic antiphospholipid syndrome, or severe flare-ups of systemic lupus erythematosus (SLE).
- Immunization against *Neisseria* species is recommended for patients who require dosing with eculizumab.
- Antibody targeting the lymphocyte integrin addressin $\alpha_4\beta_1$ (natalizumab) has been shown to be of benefit in managing multiple sclerosis (MS) and inflammatory bowel disease (IBD) but is associated with a risk of central nervous system (CNS) JC virus activation (progressive multifocal leukoencephalopathy [PML]).
- Antibody targeting the $\alpha_4\beta_7$ integrin (vedolizumab) selectively inhibits trafficking of lymphocytes into the intestinal lamina propria and is of benefit in the management of IBD.

Eculizumab, a humanized IgG2/4κ mAb with specificity for C5, blocks the generation of C5a and C5b by the C5 convertase. The resulting failure to generate C5b impairs assembly of the C5b-9 terminal attack complex, and failure to generate C5a diminishes complement pathway mediated recruitment of phagocytic cells. Since both C5a and C5b-9 have potent procoagulant activity at sites of inflammation, complement activation is hypothesized to be critical to the generation of intravascular thrombi in thrombotic microangiopathy syndromes, including atypical hemolytic–uremic syndrome (aHUS), catastrophic anti-phospholipid syndrome, and thrombotic microangiopathy that may be seen in SLE. Eculizumab is currently approved for use in patients with aHUS but has also been reported to be of benefit in patients with these other complement activation–mediated thrombotic syndromes.[55-57]

Eculizumab inhibits terminal complement activation and therefore renders patients vulnerable to infection with encapsulated organisms. Life-threatening and fatal meningococcal infections have occurred in patients who received eculizumab, and meningococcal vaccination is recommended at least 2 weeks prior to receiving eculizumab. In cases where the risks of delaying eculizumab therapy outweigh the risk of developing a meningococcal infection, meningococcal vaccine should be administered as soon as possible. However, current meningococcal vaccines do not protect against serogroup B strains of *Meningococcus,* and thus immunized patients are still at risk of infection by this strain.

TABLE 89.3 Recombinant Inhibitors of Complement Activation and Molecules Mediating Cell Migration

Molecule	Construct	Half-Life	Dosing (Maintenance)
Eculizumab	anti-C5 (humanized IgG2/4κ)	8–15 days	300–1200 mg intravenously (IV) every 1–2 weeks
Natalizumab	anti-$\alpha_4\beta_1$ (humanized IgG4κ)	7–15 days	300 mg IV every 4 weeks
Vedolizumab	anti-$\alpha_4\beta_7$ (humanized IgG1κ)	25 days	300 mg IV every 8 weeks

Adhesion Molecule Inhibitors

Trafficking of phagocytic cells and lymphocytes across vascular endothelium is critical to the development of inflammatory lesions and associated tissue injury. The transmigration of cells across the endothelium is dependent on the upregulation of integrin/adhesion molecules, some of which have binding specificity for ligands (addressins) in specific organs, such as the CNS or the enteric mucosa. Strategies to decrease the influx of monocytes and/or T and B lymphocytes using biologicals that target adhesion molecules have, therefore, been deployed as treatments for several inflammatory disorders, including MS and IBD.

Natalizumab is a humanized IgG4κ mAb with specificity for the α_4 subunit of the very late activation antigen-4 (VLA-4)–integrin molecule expressed on lymphocytes and monocytes. Natalizumab blocks association of the VLA-4 $\alpha_4\beta_1$ and $\alpha_4\beta_7$ integrins with their respective vascular receptors, thereby limiting cell transmigration into tissue sites of inflammation in the CNS and in the intestinal mucosa. On the basis of the premise that administration of natalizumab blocks the interaction of T-cell $\alpha_4\beta_1$ with its addressin ligand on venules in the CNS, this therapeutic approach was validated in murine models of encephalomyelitis, and subsequent clinical trials confirmed natalizumab to be efficacious in decreasing the frequency of relapses of MS.[58] Natalizumab also inhibits the interaction of the $\alpha_4\beta_7$ integrin with mucosal addressin cell adhesion molecule-1 (MAdCAM-1) expressed on venules in the enteric mucosa and has been shown to induce remissions and prevent flare-ups of Crohn disease in patients who have failed to have an adequate response to anti–TNF-α therapy.[59]

Recent additional work in experimental allergic encephalomyelitis (EAE) models in different strains of mice suggests that natalizumab affects primarily the transmigration of Th1 cells, with much less of an inhibitory effect on the transmigration of Th17 cells.[60] As such, there may be differential efficacy of natalizumab in the treatment of Th1- versus Th17-driven subtypes of MS and/or IBD.

The major concern with regard to the use of natalizumab is the occurrence of reactivation of John Cunningham (JC) polyoma virus in patients who are carriers, resulting in progressive multifocal leukoencephalopathy (PML). This complication has a very low rate of occurrence, but it is quite debilitating and often fatal, resulting in dampened enthusiasm for the use of natalizumab. However, the risk of PML can be mitigated by limiting the duration of natalizumab treatment to 1 year in known carriers of JC virus (as defined by seroconversion) and not administering natalizumab concurrent with other immunosuppressive therapy.

Vedolizumab is a humanized mAb that specifically binds to $\alpha_4\beta_7$ integrin, blocking its interaction with MAdCAM-1 on intestinal endothelial cells. Since vedolizumab does not bind to or block the interaction of the $\alpha_4\beta_1$ integrin to its addressin ligand in the CNS, the risk of developing PML during treatment is substantially lower than that associated with the use of natalizumab. In clinical trials, vedolizumab has been shown to significantly improve disease activity and reduce flare-ups in patients with Crohn disease or UC.[61] This strategy may prove to be particularly useful in subsets of patients with IBD as well as clinical features of SLE; in these patients, use of anti–TNF-α agents may carry an increased risk of SLE exacerbation.

Inhibitors of B-Cell Activation

Identified targets for regulation of B-cell activation include growth and survival factors, such as B-lymphocyte stimulator (BLyS; BAFF) and its respective receptors (BAFF-R, transmembrane activator and CAML interactor [TACI], and B-cell maturation antigen [BCMA]); costimulatory receptors and their ligands, such as CD40/CD40-ligand; and cell surface receptors, such as CD22 or FcγRIIb, which engender inhibitory signaling when ligated. Given the prominent role of multiple autoantibodies and generalized B-cell activation in SLE, most of the clinical trials, to date, employing strategies targeting B-cell activation have been in patients with this disorder.

Belimumab is a recombinant human genome–derived IgG1 mAb with specificity for soluble (non–membrane-bound) BLyS (BAFF). Through ligation of the BAFF-R and TACI receptors on B lymphocytes, BLyS promotes the maturation of B cells into antibody-secreting plasmablasts. On the basis of the hypothesis that autoreactive B lymphocytes may have greater dependency on BLyS to survive and proliferate, a number of preclinical studies were undertaken to target BLyS using gene knock-out strategies or soluble receptor (TACI) transfections in murine models of SLE. Following encouraging results in these models, human studies using belimumab were undertaken, and improvement in SLE disease activity was demonstrated by using validated disease activity measures (SLE Disease Activity Index [SLEDAI] and British Isles Lupus Assessment Group [BILAG]) as well as additional secondary endpoints related to disease flare-ups and sparing of corticosteroid use.[62] Consistent with its mechanism of action of targeting a growth and survival factor, noted clinical improvements do not become manifest until after 6 months of treatment with belimumab. The majority of observed clinical improvements have been observed in the musculoskeletal, mucocutaneous, and serological domains of disease activity.[62] The potential effects on more severe neurological or renal domains of disease activity have not been assessed in controlled trials.

Significant decreases in the measured numbers of circulating activated B cells and plasmacytoid B lymphocytes are observed following 6 months' treatment with belimumab.[63] Transient increase in the number of circulating memory B cells is observed immediately after administration of belimumab, with numbers gradually returning to the pretreatment baseline level over the course of several months of treatment. Total numbers of circulating B cells are decreased by 20–25% following 1-year treatment periods, with no observed decreases in CD4 and CD8 T lymphocytes.[63] Levels of autoantibodies, including anti-dsDNA, anti-Smith, anti-SSA, and anti-cardiolipin, are decreased by 40–50% percent after the first year of treatment and continue to decrease over time with long-term treatment.[63] In contrast, total antibody levels decrease, on average, by only 15%, with no significant decreases in measured preexisting antibody titers to influenza, tetanus toxoid, or pneumococcal serotypes; furthermore, treatment with belimumab does not appear to have any significant effects on the primary immune responses to pneumococcal bacterial antigens.[64,65] In two major randomized trials, the frequency of infections was not shown to be increased in the belimumab treatment arms.

Receptors for BLyS (BAFF-R) and BCMA have also recently been identified on murine T-follicular helper (Tfh) cells, with ligation of BAFF-R promoting activation of Tfh and ligation of BCMA appearing to play a role in downregulation of Tfh responses. The significance of these findings in human SLE and what impact treatment with belimumab has on Tfh responses remain to be determined.[66]

On the Horizon: Other Inhibitors of B-Cell Activation

Atacicept is a recombinant human fusion protein containing the extracellular, ligand-binding portion of the receptor TACI and a modified Fc portion of human IgG. Atacicept binds both BLyS (BAFF) and a proliferation-inducing ligand (APRIL), thereby functioning as an antagonist to the ability of these two ligands to stimulate B lymphocytes. Amelioration of disease manifestations in murine SLE models employing TACI-Ig transfections provided a mechanistic rationale for pursuing human SLE studies using TACI-Ig as a therapeutic intervention; such studies are still ongoing. However, the therapeutic window with this approach may be relatively narrow, as membrane-bound TACI is the major receptor mediating Ig class switching during B-cell maturation, and excess of the soluble receptor administered over time may result in significant humoral immune deficiency as a result of decreases in IgG-secreting B cells and plasma cells.[67]

Blisibimod is a recombinant fusion polypeptide heterodimer consisting of a BlyS (BAFF)–binding domain covalently linked to the N-terminus of the Fc region of human IgG1. The tetravalent peptibody construct binds to both soluble and cell membrane–bound BlyS, with reported higher binding affinities compared with conventional mAbs, inhibiting the interaction of BlyS with BAFF-R and TACI. Blisibimod and has been shown to have biological effects in early-phase human trials, but the clinical significance of the membrane-binding attribute of blisibimod has not been determined.[68]

Anti-CD40-ligand mAb reagents interfere with the interaction of T-cell CD40L with B-cell CD40, thereby blocking costimulatory signals required for cognate T-cell help that promotes antigen-specific B-cell proliferative responses. Following favorable results with targeting of CD40L in murine SLE models, human trials with anti-CD40L were undertaken but halted in the context of observed thrombotic complications. Subsequent studies demonstrated upregulation of CD40L on platelets, with platelet aggregation occurring in the context of complement fixation to platelet membrane–bound anti-CD40L. Newer anti-CD40L

TABLE 89.4 **Recombinant Inhibitors of Lymphocyte Proliferation, Survival and Activation**

Molecule	Construct	Half-Life	Dosing (Maintenance)
Belimumab	aBLyS/BAFF (human IgG1λ)	19 days	10 mg/kg intravenously (IV) every 4 weeks
Abatacept	CTLA-4:IgG1Fc	13 days	10 mg/kg ; 500–1000 mg subcutaneously (SC) or IV every 4 weeks
Belatacept	CTLA-4:IgG1Fc	10 days	10 mg/kg IV every 4 weeks
Basiliximab	aCD25/IL-2Ra (chimeric IgG1κ)	7–9 days	20 mg IV (repeat ×1 at 4 days)

constructs employing PEGylated anti-CD40L F(ab)' that appear to be free of the effect on platelet activation/aggregation are being evaluated in human SLE trials.[69]

KEY CONCEPTS

Inhibitors of B-Cell and T-Cell Activation

- Inhibition of BAFF/BLyS (B lymphocyte stimulator) over a period of 6–12 months decreases the survival and maturation of autoreactive B cells, decreases autoantibody titers, and decreases lupus disease activity, with minimal impact on preexisting antibody titers to microbial pathogens.
- Inhibition of T-cell costimulation targeting CD80/86 and CD28 via exogenous cytotoxic T lymphocyte antigen-4 (CTLA-4):IgFc constructs is effective in suppressing disease activity in rheumatoid arthritis (RA).

Inhibitors of T-Cell Activation

Given the role of T-cell lymphocytes in orchestrating adaptive immune responses, selective inhibition of T-cell activation is an attractive target for modulating inflammatory disorders associated with immune responses to autoantigens or allografts. Blocking cell receptors for T-cell growth factors, such as IL-2, has been employed to prevent allograft rejection and therefore may be potentially of use in the management of autoimmune disorders. Since productive immune responses are not generated in the absence of effective costimulatory signals, blocking T-cell costimulation has also been an attractive target for treatment of inflammatory diseases driven by autoreactive T cells (Table 89.4).

Basiliximab

Basiliximab is a chimeric (murine/human) mAb that blocks the α chain of the IL-2R complex expressed on activated T lymphocytes, inhibiting the binding of IL-2 to IL-2R (CD25). Basiliximab is approved for and used primarily in induction regimens for prevention of rejection of transplanted allograft.[70] Uncontrolled small case series have reported manifestations of systemic sclerosis and pulmonary complications associated with amyopathic dermatomyositis responding well to (off-label) treatment with basiliximab.[71,72]

Abatacept

Abatacept (CTLA-4 Ig) is a recombinant human protein consisting of the extracellular domain of CTLA-4 linked to the Fc portion of IgG1. Prominent among the T-cell costimulatory molecules is CD28, which binds CD80/CD86 on antigen-presenting cells (APCs). In the context of T-cell activation, CTLA-4 expression is upregulated on the surface of T cells. The binding avidity of CD80/CD86 for CTLA-4 is considerably higher than that for CD28, resulting in preferential ligation of CTLA-4, thereby disrupting further costimulation as well as engendering inhibitory signaling in the T cell as a consequence of CTLA-4 ligation. Soluble CTLA-4 Ig is not bound to the surface of the T cell and therefore does not engender inhibitory signaling; rather, the much higher avidity of the construct for CD80/86 inhibits T cell costimulation through CD28 (Table 89.4).

Although the time to maximum clinical response is somewhat longer than that observed with TNF-α inhibitors, abatacept is effective in reducing disease activity and inhibiting progression of structural damage in RA that is unresponsive to treatment with methotrexate.[73] Abatacept has no direct impact on phagocytic cell responses, and its use in patients with RA may be associated with fewer bacterial infection complications relative to patients on anti-TNF therapy. It is, nonetheless, recommended that treatment with abatacept be withheld in the context of serious intercurrent microbial infections and not be used in conjunction with other biological therapies targeting inflammation. Abatacept may be associated with an increased risk of lung cancer; however, the occurrence of lymphoma in patients with RA treated with abatacept has not been shown to exceed the expected occurrence in patients with RA. In contrast to TNF-α inhibitors, use of abatacept does not appear to promote autoimmune complications and may therefore be a preferred option for treatment of patients with RA who need biological therapy and have overlapping features of SLE or other autoimmune disorders.

Belatacept is a second-generation CTLA-4 Ig, which, compared with abatacept, has higher binding to both CD80 and CD86. Currently used primarily in organ transplantation, belatacept is associated with improved patient and renal allograft survival compared with cyclosporine.[74] Although perceived to be of potential use in autoimmune disorders, studies of belatacept use in disorders, such as SLE and RA, have not yet been reported.

Inhibitors of Mast Cell Activation

Omalizumab

Omalizumab is a recombinant humanized mAb that binds to the Cε3 domain of IgE. The binding domain is the same site at which IgE normally binds to both high- and low-affinity FcεRI on mast cells and basophils; as a consequence, free IgE is prevented from binding to the mast cell FcεRI receptor. Omalizumab is specific to IgE and does not bind to IgG or IgA. Omalizumab also cannot bind to FcεRI or to IgE already attached to FcεRI and therefore does not interact with cell-bound IgE or activate mast cells or basophils. Omalizumab is most useful, and presently approved for use in, the treatment of poorly controlled asthma despite inhaled corticosteroid use and in the setting of documented sensitization to a perennial allergen in the setting of serum IgE levels ≥30 IU/mL.[75] It is also approved for use in adults and adolescents with chronic idiopathic urticaria who remain symptomatic despite H1 antihistamine treatment. Omalizumab may also decrease the severity of asthma in patients with nonatopic (intrinsic) asthma, occupational asthma, virus-induced asthma, and eosinophilic granulomatosis with polyangiitis, but its use has not been fully studied in these populations to merit approved labeling.[76] Controlled and long-term use studies of omalizumab have shown the incidence of adverse events is not significantly increased (Table 89.5).

TABLE 89.5 Recombinant Inhibitors of Mast Cell and Eosinophil Activation

Molecule	Construct	Half-Life	Dosing (Maintenance)
Omalizumab	aIgE (humanized IgG1κ)	24–26 days	150–300 mg subcutaneously (SC) every 2–4 weeks
Mepolizumab	aIL-5 (humanized IgG1κ)	16–22 days	100 mg SC every 4 weeks
Reslizumab	aIL-5 (humanized IgG4κ)	24 days	3 mg/kg intravenously (IV) every 4 weeks

Observed clinicopathological responses to treatment with omalizumab include a marked downregulation of the surface expression of FcεRI on basophils and mast cells and reductions in FcεR1-mediated production of Th2 cytokines by basophils. Markers of airway inflammation are significantly reduced, with demonstrated reductions in sputum eosinophil counts and reduced numbers of eosinophils, CD3, CD4, and CD8 T lymphocytes, B lymphocytes, IL-4–positive cells, and IgE-positive cells in the bronchial mucosa.[77]

KEY CONCEPTS

Inhibitors of IgE and IL-5R as Treatment for Severe Allergies

- Antibodies targeting the Fc binding domain of immunoglobulin E (IgE; omalizumab) are effective in the treatment of severe asthma and recurrent mast-cell mediated chronic urticaria.
- Antibodies targeting the interleukin (IL)-5R binding domains of IL-5 are effective in the treatment of resistant asthma associated with eosinophilia as well as syndromes associated eosinophil-mediated tissue injury.

Inhibitors of Eosinophil Activation

Eosinophils mediate airway inflammation in patients with asthma, contribute to vascular and organ inflammation in patients with EGPA, and may mediate organ injury in other hypereosinophilic syndromes. IL-5 is a potent cytokine mediator of eosinophil hematopoiesis and has been shown to mediate eosinophilic inflammation in the airways. Although corticosteroids are potent suppressors of eosinophil survival, proliferation, and function, biologicals targeting IL-5 or the IL-5 receptor may prove useful as steroid-sparing therapy in managing chronic disorders mediated predominantly by eosinophils.

Mepolizumab is an mAb that binds to IL-5, thereby inhibiting its binding to the alpha chain of the IL-5R complex expressed on the surface of eosinophils. Mepolizumab has demonstrated efficacy in patients with severe asthma who have blood eosinophil counts of ≥150/µL and has been approved by the US Food and Drug Administration (FDA) for add-on, maintenance treatment of severe asthma in patients who are age ≥12 years and have demonstrated hypereosinophilia.[78] However, given the impact of corticosteroids on peripheral eosinophil counts, limiting selection of patients for treatment based on eosinophil count thresholds should not be absolute in the setting of required intercurrent steroid use. Adverse events associated with use of mepolizumab include hypersensitivity reactions and possible increased occurrence of herpes zoster.

TABLE 89.6 Recombinant T Cell– and B Cell–Depleting Agents

Molecule	Construct	Half-Life	Dosing (Maintenance)
Rituximab	aCD20 (chimeric IgG1κ)	18–23 days	375 mg/m^2 intravenously (IV) per week ×4 (q4–6 months) 1000 mg IV q2 week ×2 (q4–6 months)
Ofatumumab	aCD20 (human IgG1κ)	17 days	1000 mg IV every 4–8 weeks
Obinutuzumab	aCD20 (humanized IgG1κ)	24–36 days	1000 mg IV every 2 weeks ×2
Alemtuzumab	aCD52 (humanized IgG1κ)	1–14 days	12 mg IV daily ×5 days 10–30 mg subcutaneously (SC) 3 times per week
Brentuximab-vedotin	aCD30 (chimeric IgG1κ):MMAE	4–6 days	0.3–1.8 mg/kg IV every 3 weeks

Reslizumab is an mAb that targets IL-5R binding domains of IL-5. Administered intravenously, reslizumab has been shown effective in decreasing the frequency and severity of asthma exacerbations and is approved by the FDA for use in adult patients with demonstrated eosinophilia and otherwise treatment-resistant asthma.[79] Adverse events include occasional episodes of severe hypersensitivity reactions during infusions.

On the Horizon: Anti-IL-5 Receptor Reagents

The anti–IL-5R antibody *benralizumab* blocks activation of eosinophils by IL-5 but has an additional property of depleting IL-5R–bearing eosinophils and basophils via enhanced ADCC.[80] The recombinant antibody is afucosylated, rendering a higher affinity for FcγRIII and enhanced ADCC of IL-5R–bearing cells. Studies are currently underway to confirm the clinical efficacy of benralizumab in managing asthma and to determine its utility in managing other disorders mediated by tissue infiltration of eosinophils.

B Cell– and T Cell–Depleting Agents

There are several mAb-based constructs that have been developed primarily for the treatment of lymphoid malignancies and/or prevention of transplant rejection. Since B cells have a demonstrated role in the generation of autoantibodies as well as antigen presentation to and costimulatory support for autoreactive T cells, strategies to deplete B lymphocytes have been successfully employed in the treatment of autoimmune and inflammatory diseases. In subsequent randomized trials, some of these agents (rituximab) have been shown to have efficacy and are approved for use in the treatment of both RA and ANCA-associated vasculitis syndromes. Case reports have also documented the successful use of mAb-mediated B cell– and also T cell–depleting strategies in the management of patients with severe, refractory flare-ups of SLE, autoimmune inflammatory myopathies, and GvHD (Table 89.6).

Rituximab

Rituximab is a chimeric IgG1 mAb with specificity for the B-lymphocyte surface antigen CD20, a cell-surface molecule expressed on the surface of pre-B through activated mature B cells. Rituximab induces lysis of $CD20^+$ B cells by several mechanisms, including complement activation, ADCC, and induction of apoptosis. Induction regimens using four weekly doses or two larger doses administered 2 weeks apart appear to be equally effective at effecting the depletion of circulating $CD20^+$ B cells, which can last up to ≥9 months after a single course of therapy. Treatment with rituximab has been shown to cause significant transient decreases in inflammatory CD4 T cells that express IL-17; the extent to which this is caused by an indirect consequence of $CD20^+$ B-cell depletion or depletion of identified subsets of $CD4^+CD20^+$ T cells is uncertain.[81,82]

Approved for use in patients with RA failing to respond to initial disease-modifying antirheumatic drug (DMARD) therapy, rituximab has been shown to improve the signs and symptoms of disease, functional status, and quality of life and to slow radiographic progression of disease in patients with RA.[83] Greater clinical responses are observed among patients with RA who are seropositive for rheumatoid factor (RF) and/or anticitrullinated peptide (CCP) autoantibody compared with patients seronegative for RF or CCP.[84] The optimal treatment schedule for use of rituximab in RA remains to be determined, but retreatment is generally recommended no sooner than 6 months following initial treatment for patients in whom the disease flares up in association with recovery of B-cell counts and for those who had initially responded to rituximab therapy.

Rituximab has also been used with considerable success and is approved for use in the management of ANCA-associated and other vasculitis syndromes. Rituximab plus glucocorticoid therapy was shown to be as effective as cyclophosphamide in the treatment of patients with granulomatosis with polyangiitis (GPA) or microscopic polyangiitis (MPA).[85] In a subgroup of patients with relapsing ANCA vasculitis, rituximab was, in fact, superior to cyclophosphamide in inducing disease remissions.[85] In patients with cryoglobulin syndromes occurring in the context of either HCV infection or lymphoma, use of rituximab has been shown to decrease cryoglobulin and constituent Ig titers and hasten resolution of cryoglobulin manifestations, including skin ulcers, glomerulonephritis, peripheral neuropathy, arthritis, and/or hyperviscosity complications.[86]

Although not yet formally approved, rituximab has been used with reported success in the management of other autoantibody-mediated disorders, including SLE, primary Sjögren syndrome, inflammatory myopathy, chronic inflammatory demyelinating polyneuropathy (CIDP), MS, and pemphigus.[87-92]

Despite the potential for immunodeficiency-related to depletion of $CD20^+$ B cells, only minimal increases in serious or opportunistic infections have been reported in patients with RA or ANCA vasculitis treated with repeated cycles of rituximab. Mild decreases in the overall levels of serum Igs may be observed during treatment, but Ig levels are rarely depleted, likely due to the preservation of more mature B cells and plasma cells that have lost surface expression of CD20. However, if used concomitantly with other immunosuppressive agents impacting lymphocyte proliferation, significant hypogammaglobulinemia may ensue over time as a result of the inability to replenish the plasma cell compartment.[93] Use of rituximab carries a safety warning related to an observed increased risk of viral infections, including CMV, herpes simplex virus (HSV), varicella-zoster virus (VZV), HBC, and JC virus. Reactivation of JC virus, latent in more than 80% of the general population, can occur in immunosuppressed patients to cause PML, a fatal demyelinating disease of the CNS. Cases of PML have been reported among patients with hematological malignancies, SLE, and RA who were treated with rituximab, but PML usually occurs in the context of other therapies impacting lymphocyte survival and proliferation.[94]

Ofatumumab

Ofatumumab is a fully human mAb that binds to an epitope encompassing both small and large loops of the extracellular domain of the CD20 cell surface antigen on B lymphocytes. The binding epitope of ofatumumab is distinct from that of rituximab, residing more proximal to the cell membrane. In comparative studies with rituximab using chronic lymphocytic leukemia (CLL) cells, ofatumumab elicits similar ADCC but elicits greater complement-dependent cytotoxicity (CDC) because of the greater proximity of the binding site to the cell membrane and/or binding affinity to CD20 epitopes.[95]

Obinutuzumab

Obinutuzumab (GA101) is a recombinant, humanized, and glycoengineered type II CD20 mAb of the IgG1 isotype that targets the extracellular loop of the CD20 transmembrane expressed on the surface of pre-B and mature B lymphocytes. Relative to rituximab and ofatumumab, glycoengineering of the Fc portion of obinutuzumab results in a higher affinity for FcγRIII receptors on immune effector cells, such as NK cells and phagocytic cells. *In vitro* studies with B-cell lymphoma–derived cell lines show that compared with rituximab and ofatumumab, obinutuzumab mediates greater induction of direct cell death and effector cell–mediated ADCC and cellular phagocytosis. However, compared with rituximab and ofatumumab, CDC is significantly reduced with obinutuzumab.[96]

Alemtuzumab

Alemtuzumab is an mAb with specificity for CD52, an antigen present on the surface of B and T lymphocytes as well as the majority of monocytes, macrophages, NK cells, and a subpopulation of neutrophils. Approved for use in the treatment of B-cell CLL and relapsing-remitting MS, alemtuzumab has also been used with success for the treatment of T-cell prolymphocytic leukemia, prevention and treatment of acute GvHD, and prevention of allograft rejection. Alemtuzumab has been used off-label with reported success in the treatment of patients with severe SLE and Behçet disease refractory to other treatments.[97,98] Despite the depletion of T lymphocyte, B lymphocyte, NK cell, and monocyte populations following treatment, reported rates of serious infections following treatment with alemtuzumab are not significantly increased compared with other immunosuppressive regimens employed to manage the disorders for which it is used. However, there is a significant occurrence of secondary autoimmunity following use of alemtuzumab, most often manifest as autoimmune thyroid disease and immune thrombocytopenia. The observed autoimmune complications may be caused by homeostatic proliferation of self-reactive memory T cells in the absence of an effective T regulatory response during immune reconstitution.[99]

Brentuximab Vedotin

Brentuximab vedotin (BTX-v) is an mAb with specificity for CD30 that is covalently linked to the antitubulin agent monomethyl auristatin E. Expressed on subpopulations of T lymphocytes, some populations of B cells, and most notably Hodgkin

KEY CONCEPTS

B-Cell and T-Cell Depletion Strategies

- Monoclonal antibody (mAb)–mediated depletion of CD20$^+$ B lymphocytes is effective in the treatment of antineutrophil cytoplasmic antibody (ANCA)–associated vasculitis, cryoglobulin syndromes, and rheumatoid arthritis (RA); the best responses in patients with RA are those with significant elevations in rheumatoid factor (RF) and anti–citrullinated peptide (CCP) antibodies.
- There are subsets of T cells that also express CD20, and part of the clinical efficacy of anti-CD20 mAb reagents may be attributed, in part, to depletion of these subsets of T cells.
- mAb reagents with greater binding affinity and binding sites more proximate to the cell membrane appear to have greater efficacy depleting CD20$^+$ lymphocytes.
- Depletion of CD20$^+$ lymphocytes has been associated with reactivation of hepatitis B virus (HBV), and vigilance for latent HBV reactivation is prudent when using anti-CD20 mAb reagents.
- mAb reagents targeting CD52 deplete both T-helper cells as well as regulatory T cell (Treg) subsets; imbalances in relative homeostatic T-cell reconstitution following treatment may result in autoimmune complications.

disease Reed-Sternberg cells, BTX-v is presently approved for use in the treatment of patients with Hodgkin lymphoma as well as of those with refractory non-Hodgkin lymphomas expressing CD30. Enhanced expression of CD30 on CD8 T cells as well increased levels of sCD30 have been observed in patients with active SLE, and BTX-v is currently being evaluated for potential clinical efficacy in the management of SLE.[100]

MULTIPLE-CHOICE QUESTIONS

1. A patient has symmetrical inflammatory arthritis and photosensitive skin rashes. The serological profile is notable for positive rheumatoid factor (RF), positive anti–citrullinated peptide (CCP) antibody, and positive antinuclear antibody (ANA) (titer 1:640). She is diagnosed with rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE) overlap. Treatment with weekly dosing with methotrexate and treatment with an antimalarial (hydroxychloroquine) fails to achieve resolution of the joint inflammation. Which of the following biological treatments would be most appropriate to treat the ongoing joint inflammation?
A. Etanercept
B. Adalimumab
C. Certolizumab
D. Rituximab
E. Belimumab

2. A patient with congestive heart failure, chronic kidney disease, and diabetes is hospitalized with manifestation of volume overload and fever. *Escherichia coli* bacteremia from urinary sepsis is confirmed. Appropriate parenteral antimicrobial therapy and diuresis are initiated, resulting in clinical improvement. But on the third hospital day, the patient develops pain, swelling, and tenderness in the left great toe, midfoot, and ankle. An ankle arthrocentesis is performed, and it demonstrates of urate crystals in the joint fluid; gram staining is negative for bacterial organisms. Given the reluctance to prescribe nonsteroidal antiinflammatory drugs (NSAIDs) or corticosteroids to manage the acute polyarticular gout because of this patient's comorbidities, which of the following biologicals would be MOST appropriate to use in this setting?
A. Canakinumab
B. Anakinra
C. Infliximab
D. Abatacept
E. Mepolizumab

3. A patient with inflammatory bowel disease (IBD) has increased weight loss in association with ongoing abdominal pain and diarrhea despite use of adalimumab. Abdominal imaging confirms evidence of significant bowel inflammation involving multiple segments of the ileum. Which of the following of the following biologicals would be MOST appropriate to prescribe?
A. Secukinumab
B. Tocilizumab
C. Etanercept
D. Natalizumab
E. Vedolizumab

4. A 23-year-old patient has a history of asthma, for which an inhaled corticosteroid preparation and a beta-agonist have been prescribed, and recurrent urticaria, for which daily doses of an antihistamine (loratadine) and a leukotriene receptor antagonist (montelukast) have been prescribed. Although occasional use of a rescue inhaler is required, the asthma is felt to be reasonably well controlled; however, there are recurring episodes of urticaria and angioedema. Laboratory studies are notable for a peripheral eosinophil count of 210/mm^3 and serum immunoglobulin E (IgE) of 110 IU/mL. Complement level C4 is 12 mg/dL (normal >14), complement C3 is normal, and CH50 is normal. Tests for antinuclear antibodies (ANAs) and antineutrophil cytoplasmic antibodies (ANCAs) are negative. Addition of which of the following would be MOST useful in managing this disorder?
A. Omalizumab
B. Rituximab
C. Mepolizumab
D. Reslizumab
E. Eculizumab

5. A patient with an undifferentiated autoimmune connective tissue disease has ongoing severe inflammatory manifestations affecting the central nervous system, lungs, joints, and kidneys despite use of standard therapy, prompting consideration of more aggressive cell-depleting immunosuppressive therapy. Use of which of the following is MOST likely to be associated with the reemergence of autoimmune manifestations following immune reconstitution?
A. Rituximab followed by belimumab
B. Obinutuzumab followed by belimumab
C. Alemtuzumab
D. Brentuximab vedotin
E. Cyclophosphamide followed by low-dose IL-2

Vaccines

Sarah Kabbani, Mark J. Mulligan

It might be fair to imagine that the field of vaccinology began with the first recognition that a person who survived an infection was much less likely to suffer from that disease in the future in comparison with a person who had not previously had the disease. That is, the infectious disease, if it did not kill the person, resulted in an experienced, protected state. Today we would say that the protected survivor had immunity.

Vaccines are clinically simple but immunologically complex preventive or therapeutic interventions that can dramatically reduce morbidity and mortality caused by infectious diseases in children, adolescents, adults, and seniors. In recent years, vaccinations against other categories of disease have become an increasingly active area of research (*e.g.,* cancer and dementia). In addition, vaccines against microbes are increasingly appreciated for their potential role in the medical field's heightening battle against antimicrobial-resistant bacteria. For example, the protein conjugate pneumococcal vaccine was shown to reduce the incidence of antibiotic-resistant pneumonia.[1] Preventing an illness through vaccination obviates the need to treat a bacterial infection with antibiotics, thereby avoiding potential induction of antibiotic resistance in either the targeted pathogenic bacterium or the patients' healthy microbiota.

Another important area of recent emphasis has been the double power of vaccinations for pregnant women, protecting two—mother and infant—against the targeted pathogen (e.g., pertussis[2] or influenza[3,4]). In addition, a critical need for pre-pregnancy vaccination to protect pregnant women and their fetuses ahead of and during the highly vulnerable first trimester of pregnancy is currently underscored by acquisition of Zika virus infections during pregnancy with resulting microcephaly and other birth and developmental anomalies.[5-8]

Although senior citizens (>65 years of age) experience high proportions of the total morbidity and mortality for several vaccine preventable diseases (*e.g.,* seasonal influenza, pneumococcal disease, herpes zoster) as a result of immunosenescence, they are least able to mount their own protective immune responses after vaccination. Community protection (also termed *herd immunity*) of seniors by vaccination of children, who are the primary spreaders of many vaccine-preventable infectious diseases, and younger adults can provide dramatic reductions in infectious disease incidence in seniors—for example, the reduction in pneumococcal disease in seniors after the introduction of pneumococcal conjugate vaccine for children.[9,10] Despite suboptimal vaccine responses with aging, several vaccines are specifically recommended for seniors (see Fig. 90.3) and some of the vaccines for seniors now employ novel strategies to enhance the immunosenescent response, such as high doses of influenza antigen[11,12] or coformulation of virus antigen with an adjuvant.[13,14]

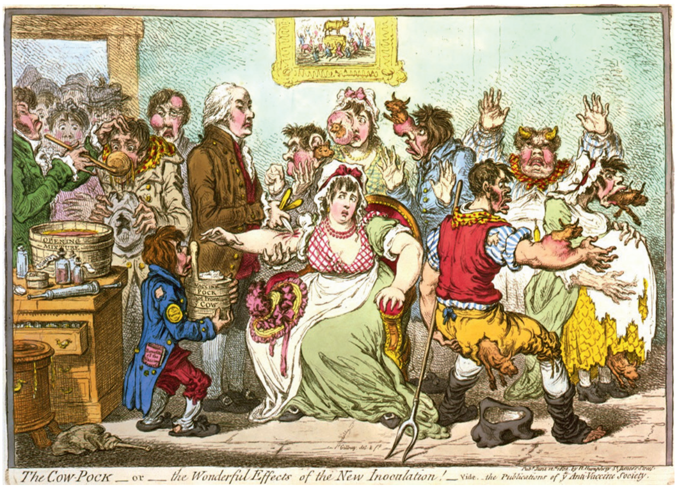
That vaccines have a societal benefit in addition to the individual protection provided to the vaccine recipient is a special and gratifying aspect of this highly valuable biomedical intervention. Vulnerable community members whose immune systems are unable to respond well to vaccines (newborns, immunocompromised persons, older adults) or are unable to receive vaccines (because of allergy or a medical contraindication) depend on immunization of surrounding community members for protection against vaccine preventable diseases. The vaccinated community becomes an immunological cocoon or wall of protection for these vulnerable members of society.

This chapter first reviews selected events in the history of vaccination, both distant and recent. The remarkable accomplishments that have resulted from programs of vaccination to date are then highlighted. We also describe important recent milestones and changes in vaccine development strategies that have the potential to revolutionize the field and offer great hope for providing solutions for unmet vaccine needs. Current vaccine recommendations are then summarized. Finally several present and future challenges for the field of vaccinology are discussed.

HISTORY OF VACCINES

The earliest known vaccines for which records have been identified were against smallpox and were used in Asia early in the second millennium.[15] Of course, they were not called "vaccines." The practice was called *variolation* and involved exposing, usually through the intranasal route, a smallpox-susceptible (not previously infected) person to material from the dried scabs of a person who had had smallpox. If the recipient survived, he or she was protected against future smallpox disease. Since natural smallpox had a 30% mortality rate and variolation had a lower (≈1%) mortality rate, this ancient practice was an early example of weighing the risk-to-benefit ratio for a human health intervention. By 1700, variolation was employed in a number of societies in Africa, India, and the Ottoman empire, and it was in use in England and France in the 1700s.[16] The practice of variolation was not without risk and sometimes caused outbreaks of a mild form of the disease. One of the many who died as a result of variolation was a son of England's King George III.

In 1796, an English physician was searching for a safer alternative to variolation. This physician was to become known as the father of vaccinology—Edward Jenner. He performed a smallpox vaccination experiment on James Phipps on May 14, 1796, using as vaccine cowpox pus from the lesions on the hands of Sarah Nelmes, a milkmaid.[17] Dr. Jenner then collected lesion material from a patient with smallpox and used this as the viral challenge



The Cow-Pock — or — the Wonderful Effects of the New Inoculation! — Vide. the Publications of ye Anti-Vaccine Society.

FIG 90.1 **Antivaccination Caricature by James Gillray From 1802 Entitled "The Cow-Pock—or—The Wonderful Effects of the New Inoculation!" Directed Against Jenner and His Work to Promote Smallpox Vaccination.** (Originally by James Gillray, The Cow-Pock—or—the Wonderful Effects of the New Inoculation! (1802). vide. the Publications of the Anti-Vaccine Society. Print (color engraving) published June 12, 1802 by H. Humphrey, St. James's Street. Library of Congress, Prints & Photographs Division.)

stock. Young Phipps survived both the vaccination and the challenge, and Jenner first reported his experiment in 1797 in a short communication to the Royal Society. After Jenner's initial report submitted for publication was rejected, he added a few more cases of his vaccine experiment (including one on his own son), and in 1798, he reported his findings in a self-published booklet entitled "An inquiry into the causes and effects of the variolae vaccinae, a disease discovered in some of the western counties of England, particularly Gloucestershire, and known by the name of the cow pox."[18]

CLINICAL RELEVANCE

Why vaccines are critical interventions for every medical practice

- Vaccines are highly effective interventions for preventing infectious diseases and have public health importance.
- Both individual protection and community (herd) immunity result from vaccination programs.
- The reductions in disease burden (morbidity and mortality) achieved through implementation of childhood vaccination programs are extraordinary.
- In the last several years, new adolescent and adult vaccines have become available and are now recommended. Vaccination is not just for children anymore.
- Clinicians of all specialties should take vaccine histories and provide access to vaccines relevant to their patients' ages and medical conditions. Access can be provided through referral or by stocking and administering the indicated vaccines.

This self-published report and Jenner's subsequent use of cowpox vaccination were greeted with mixed reaction. Jenner's work was considered controversial by some because of the introduction of a cow virus into humans. A famous satirical cartoon by James Gillray depicts cow parts emerging from vaccinated persons (Fig. 90.1). Other opponents of vaccination were those with financial interests in lucrative variolation practices. When vaccination in England was made compulsory by the Vaccination Act of 1853, an organized antivaccination movement arose almost immediately.[19] Incredibly, even in the present day, despite all the evidence supporting the safety and effectiveness of licensed vaccines, organized antivaccination movements continue to challenge contemporary clinicians and public health officials. The explosive growth of the Internet in the last 2 decades has made it relatively easy to self-publish anything and everything, and this has resulted in rapid and wide dissemination of misinformation about vaccines, antivaccination propaganda, and pseudoscience that obstructs traditional scientific evaluation and further feeds the general public's fears and misunderstandings.

It is worth noting that Jenner's work of 220 years ago encapsulates many of the elements of today's translational vaccinology.

KEY CONCEPTS

Edward Jenner's Work Relevant to Translational Vaccinology Today

- **Disease burden, surveillance, epidemiology:** A significant and unacceptable burden of smallpox disease drove development of a safer intervention to improve health.
- **Innovation:** Jenner's innovation resulted from the need for an improved biomedical intervention given the significant risk of harm associated with the centuries old variolation practice.
- **Clinical insight:** An observation that dairymaids who had recovered from an occupational illness (cowpox) were seldom affected by smallpox led to Jenner's promotion of smallpox vaccination. The observation of the protected state (immunity) in dairymaids led to a concept that was tested and promoted by Jenner.
- **Postvaccination challenge:** After the vaccination procedure, Jenner's subjects were subsequently intentionally exposed to (challenged with) wild-type smallpox and observed for safety and disease outcomes. This would not be permissible today in smallpox research, although human challenge experiments are performed for certain self-limiting or treatable infectious diseases.
- **Presentation of experimental results:** To disseminate the scientific information and advocate for wider vaccination deployment, Jenner presented his work to the Royal Society. He self-published his manuscript after it was rejected by the Society.
- **Branding:** The name "vaccination" was applied to the intervention. *Vacca* is the Latin word for "cow."
- **Antivaccination movement and conflicts of interest:** Jenner experienced significant opposition to his vaccine from groups opposed to the new technique and from individuals who had vested interests in variolation practices and stood to lose their business if the concept of vaccination caught on.

Although Jenner's smallpox challenge experiment would not be approved by today's institutional research boards (IRBs, or ethics committees), certain human challenge studies remain both acceptable and valuable today. The postvaccination challenge experiment can be an important process to efficiently obtain preliminary protective efficacy information for a vaccine and has been shown in early-phase clinical trials to be safe, well tolerated, and immunogenic. Human challenge studies are performed for self-limiting and/or treatable infections to study vaccine protection or to characterize host response to infection in detail (*e.g.*, influenza,[20] primary dengue,[21] norovirus,[22] and malaria[23]). A human challenge experiment can rapidly provide feedback to vaccine developers and public health officials to help prioritize resource-intensive field trial evaluations of promising candidate vaccines. If an encouraging preliminary efficacy signal is observed in a postvaccination human challenge trial, it can provide additional evidence and justification to funding agencies for proceeding to large and expensive field trials. This is particularly advantageous in the context of an epidemic, where rapid vaccine development and deployment are needed for optimal impact on morbidity and mortality. A contemporary example is Zika virus vaccine development—for which postvaccination human challenge experiments are under consideration.

The history of vaccination entered its second phase in the nineteenth century. The miasma theory (which postulated that infectious diseases were caused by a noxious form of bad air) was gradually replaced by the development of the germ theory (according to which infectious diseases were caused by microorganisms too small to be seen without magnification). Animal experiments and laboratory cultivation of microbes were key advances relating to the germ theory in the second half of the nineteenth century. Robert Koch (1843–1910) and the great French chemist Louis Pasteur (1822–1895) made significant contributions through their many key observations and experiments in both agricultural and human infectious diseases and vaccines. Koch's famous four postulates laid out the requirements for establishing causality of infectious diseases by microbes and proved that *Bacillus anthracis* was the cause of anthrax. This provided the first proof of a microbial etiology of a specific disease.[24] Pasteur's work was credited with saving the silkworm industry, reducing the spoilage of wine, stopping epidemics among agricultural herds, and the development of vaccines against human infectious diseases, such as rabies and anthrax. Through attenuation or inactivation of wild-type microbes, Pasteur produced vaccines that induced protection against a number of diseases. He performed a number of classic vaccination and challenge experiments in farm animals; these experiments were designed to show that in experimental challenges, his altered (attenuated or inactivated) cultures of microbes could be delivered as vaccines that offered protection to susceptible animals and herds against organisms that could be devastating, including veterinary pathogens, such as chicken cholera and anthrax, and human pathogens, such as rabies.[24]

Twenty-first century vaccinology is a multitasker's dream, encompassing multiple fields, including microbiology, immunology, medicine, epidemiology, statistics, policy, manufacturing, molecular biology, public health, and ethics. But vaccinology was not always so. Certainly in the 1700s and earlier centuries, the variolators and the great Jenner knew they had created a protected condition in their patients through their intervention only if their patient survived that intervention. But they had no specific knowledge of the killed or attenuated microbe they were administering, of the virulent microbe they were protecting against, or of the immune system changes induced in the bodies of their patients (or even of the existence of the immune system).

In the nineteenth century, Pasteur and Koch certainly knew that microbes were the cause of infectious diseases and that weakened forms of microbes (vaccines) could create a protected state after administration to livestock or humans. But they had no specific knowledge of the changes produced in the vaccine recipient's immune system.

In the early twentieth century, passive immunization was developed as a therapy for infectious diseases. Active immunization involves administering a vaccine to trigger a subsequent cascade of changes in the patient's own immune system leading to a protected state (immunity), whereas passive immunization is direct transfer of the protective immune effector molecules (antibodies) taken from an immune donor patient or animal, without administering a vaccine to the patient. Early work by Emil von Bering (1854–1917) with small-animal serum therapy experiments led to the development of human serum therapies for passive immunization. In 1900, von Bering used horse sera from immune horses to cure and prevent diphtheria caused by *Corynebacterium diphtheria*. The very first Nobel Prize in Physiology or Medicine in 1901 was awarded to von Behring "for his work on serum therapy, especially its application against diphtheria, by which he has opened a new road in the domain of medical science and thereby placed in the hands of the physician a victorious weapon against illness and deaths."[25]

During the second half of the nineteenth century, scientists were discovering the immune system's defense mechanisms. The Nobel Prize in Physiology or Medicine for 1908 was awarded to Ilya Ilyich Mechnikov (1845–1916) and Paul Ehrlich (1854–1915) "in recognition of their work on immunity" and for establishing the concepts of cell-mediated and humoral immunities. Mechnikov described the abilities of certain white blood cells (WBCs) of starfish larvae to perform phagocytosis or engulfment and destruction of harmful bacteria and other microbes. Ehrlich worked on serum therapy against diphtheria with von Bering and speculated that certain WBCs have receptors that bind toxins formed by bacteria, and when these receptors separate from the cells, they become antibodies.

In 1924, Gaston Ramon (1886–1963) developed the method of chemical inactivation of bacterial toxins with formaldehyde and heat to produce toxoids of the pathogenic toxins of diphtheria and tetanus, producing safer vaccine antigens that retained their immunogenic potential.

The Nobel Prize in Physiology or Medicine 1951 was awarded to Max Theiler (1899–1972) "for his discoveries concerning yellow fever and how to combat it." Theiler, through passage of yellow fever virus in mice, developed an attenuated live yellow fever virus variant designated 17D, which became a highly effective vaccine.

Other innovators who exploited the potential of microbial cultivation were Enders et al., who, in the 1940s, discovered methods for cultivation of poliovirus in cell culture. This removed the obstacles in the field of poliovirus vaccine development, which then advanced relatively quickly after decades of very slow progress. Laboratory growth of poliovirus permitted the development of both the inactivated polio vaccine (IPV; Salk, licensed in 1955) and the live attenuated oral polio vaccine (OPV; Sabin, monovalent licensed in 1961, trivalent in 1963).[26] As a result of these vaccines, still in use today, poliovirus type 2 was eradicated in 1999, and no wild-type poliovirus type 3 has been detected since 2012. Only poliovirus type 1 is still endemic in 2016 in just two countries, Pakistan and Afghanistan. The progress toward polio eradication is impressive, as the final steps are being taken, but final eradication will require great persistence in vaccinating the populations in these countries and sustained attention to surveillance.[27]

In their considerations of the power of vaccines and other preventive interventions to protect humans and reduce infectious disease incidences, public health officials have described the stages leading to the ultimate goal of ending human suffering caused by infectious diseases: control, elimination, eradication, and extinction of infectious diseases (Table 90.1).[28] The long road, which will hopefully culminate soon in poliovirus eradication, began with successful poliovirus cultivation in cells in the laboratory. "For their discovery of the ability of poliomyelitis viruses

TABLE 90.1 Stages of Reduction of Infectious Disease Incidence by Vaccination and Other Preventive Interventions

Control. The reduction of disease incidence and prevalence to a locally acceptable level as a result of vaccination and/or other interventions; continued interventions are needed to maintain the reduction. *Example:* diarrheal diseases.

Elimination of disease. Reduction to zero of the incidence of a specified disease in a defined geographical area as a result vaccination and/or other interventions; continued measures are required. *Example:* neonatal tetanus.

Elimination of infection. Reduction to zero of the incidence of infectious disease in a defined geographical area as a result of vaccination and/or other interventions; continued measures to prevent reestablishment of transmission are required. *Example:* poliomyelitis elimination from North America.

Eradication. Permanent reduction to zero of the worldwide incidence of infection caused by a specific agent as a result of vaccination and/or other prevention efforts; interventions are no longer needed. *Example:* smallpox.

Extinction. An infectious agent no longer exists in nature or in the laboratory. *Example:* none.

(Adapted from Dowdle WR. The principles of disease elimination and eradication. Bull W H O 1998;76 Suppl 2:22–5.)

to grow in cultures of various types of tissue," John Enders, Thomas Weller, and Frederick Robbins jointly received the Nobel Prize in Physiology or Medicine in 1954.[29]

Recognition and subsequent exploitation in vaccines of key antigenic substructures rather than whole microbes was another technical advance. For example, the studies of Oswald Avery (1877–1955), Rebecca Lancefield (1895–1981), and others of the polysaccharide capsules of *Streptococcus pneumoniae*[30,31] and the M proteins of the Streptococcus species,[32] respectively, led to the characterization, isolation, and serotyping of these bacterial structures and their recognition as key antigens in immunity to streptococcal diseases. Such observations eventually led to safer vaccination with components (subunits) of pathogens, as opposed to entire microbes (*e.g.,* the bacterial polysaccharide capsules from *S. pneumoniae* or *Neisseria meningitidis,* or the viral surface antigens [hemagglutinins, or HA] in influenza split-virus vaccines). When delivered as vaccines, these isolated microbial components produced protective antibodies and cellular immune responses in vaccinated hosts but did not cause the disease induced by the complete wild-type organisms.

The great influenza A/H1N1 pandemic of 1918 ("Spanish flu") caused an estimated 50 million deaths globally. This led to efforts to develop vaccines against influenza, and in 1933, the virus that causes influenza was identified.[33] That discovery quickly led to the first-generation live attenuated and killed monovalent influenza vaccines. A bivalent vaccine was produced in 1942 after the discovery of a second influenza type, type B. The ability to grow influenza viruses in embryonated hen's eggs facilitated vaccine production and provided the basis for killed and split-virus influenza virus vaccines that came into use in the 1940s.[33] Over the following years that followed, there was increasing awareness of the multiple types of influenza (A, B, and C), subtypes of influenza A (*e.g.,* A/H1N1, A/H3N2), and lineages of influenza B (Victoria and Yamagata). In addition, recognition that influenza virus *antigen drift* (caused by changes in the two surface proteins HA and neuraminidase [NA]) could lead to vaccine mismatch with an altered circulating strain and thus decreased vaccine effectiveness was first described when the US Army's A/H1N1 vaccine, which had been successfully used for several years, became significantly less effective in 1947 as a result of antigenic drift. In 1958, the type A virus, which was circulating at that time, entirely changed its HA and NA proteins to new subtypes, a process termed *antigenic shift.*[33] With increased recognition that it was necessary to regularly update the vaccine composition to match the changing circulating strains, in 1973, the World Health Organization (WHO) began providing annual recommendations for the composition of the seasonal influenza vaccine based on the current circulating subtypes and strains. In 1978, the first trivalent vaccine was licensed (two influenza A strains and one influenza B strain). Beginning in 2013, the WHO began including a second type B strain and recommended four vaccine strains annually (A/H3N2, A/H1N1, B/Victoria, and B/Yamagata), which enabled production and licensure of the new quadrivalent influenza vaccines.

Several other live, attenuated viral vaccines, such as measles, mumps, and rubella vaccine (MMR), were developed in the second half of the twentieth century and became staples of childhood vaccination programs both in the United States and globally. Serial passages of wild-type viruses led to viral adaptation for growth in cell cultures and a diminished ability to cause disease in humans. Importantly, the cell culture–passaged viruses that were useful as vaccines were not only well tolerated and safe in humans, but they retained the ability to produce protective immune responses. Later in the twentieth century, the development of the Oka strain of the varicella-zoster virus led to live attenuated vaccines for both chicken pox in children and herpes zoster in seniors.

KEY CONCEPTS

Historical Highlights

- Edward Jenner promotes use of the smallpox vaccine in 1798.
  - "Morbid matter of various kinds, when absorbed into the system, may produce effects in some degree similar; but what renders the cow-pox virus so extremely singular is that the person who has been thus affected is forever after secure from the infection of the small-pox; neither exposure to the variolous effluvia, nor the insertion of the matter into the skin, producing this distemper."[18]
- World Health Organization certifies eradication of smallpox from the world in 1980.
  - "The world and its peoples have won freedom from smallpox, which was a most devastating disease sweeping in epidemic form through many countries since earliest time, leaving death, blindness and disfigurement in its wake and which only a decade ago was rampant in Africa, Asia and South America."[40]

The decades following World War II have been described as a golden age for vaccinology. Maurice Hilleman (1919–1985) developed a number of vaccines against viruses while working for large pharmaceutical companies during the middle of the twentieth century. His highly productive career included inventions of vaccines against measles, mumps, and rubella; *Haemophilus influenzae* type b; hepatitis A; hepatitis B; and chickenpox.[34]

The polysaccharide vaccines developed for the prevention of bacterial diseases caused by *H. influenzae, N. meningitidis,* and *S. pneumoniae* were welcome advances. Over time it was recognized that these polysaccharide antigens were T-cell independent because they contained no peptide/protein antigens. Furthermore, unlike T cell–dependent protein antigens, these carbohydrate antigens failed to produce B-cell memory responses. The polysaccharide vaccines could not be used in neonates because infants cannot mount an effective immune response against polysaccharide antigens alone. The brilliant technical development that overcame this disadvantage for bacterial polysaccharide vaccines was covalent coupling, or conjugation, of the glycan structure to a protein carrier, such as tetanus or diphtheria toxoids. This maneuver converted the T cell–independent polysaccharide vaccines into T cell–dependent protein–polysaccharide conjugate vaccines, and this resulted in B-cell memory, much improved immunity, usefulness in newborns, and even reduction in nasopharyngeal carriage (not seen with the pure polysaccharide vaccines), thus creating herd immunity.[35] The observation that protein conjugation to polysaccharide improved the immune response was made first by Avery and Goebel in 1929[36] but was not utilized until Robbins et al. conjugated the *H. influenzae* type B polysaccharide.[37]

Increasingly in the late twentieth century and early twenty-first century, the molecular biology revolution and the fundamental dissections of the innate and adaptive immune responses are being exploited to produce new-generation vaccines. Some of these dimensions are discussed further in the sections below.

ACCOMPLISHMENTS OF VACCINATION

It is generally believed that elimination of an infectious disease from circulation in human populations through vaccination can only be achieved in the case of pathogens that have no animal reservoir and vaccination against which induces long-lasting immunity (see Table 90.1). Smallpox eradication was, in fact, achieved after a successful worldwide vaccination campaign and is the signature accomplishment of vaccination. The fields of medicine and public health celebrate this remarkable vaccination success as an example of the power of vaccination to improve human health. Smallpox was an infection that was a scourge of humanity for millennia, disfiguring and blinding survivors and killing 30% of those infected.[38] The last reported case of smallpox in the United States was in 1949. The world's last known patient with naturally occurring smallpox was Ali Maow Maalin in Somalia in 1977.[39] After the disease was eliminated, routine vaccination of the general public against smallpox was discontinued because it was no longer necessary for prevention of this disease. In 1972, the United States halted routine smallpox immunization of the American public. In 1980, the WHO certified that smallpox had been eradicated: "The world and its peoples have won freedom from smallpox, which was a most devastating disease sweeping in epidemic form through many countries since earliest time, leaving death, blindness and disfigurement in its wake and which only a decade ago was rampant in Africa, Asia and South America."[40] Small quantities of smallpox virus are stored in secure research laboratories at the Centers for Disease Control and Prevention (CDC, Atlanta, GA) and in Russia.

It has been over 200 years since Jenner's self-published report on smallpox vaccination.[17] As the dawn of the third millennium approached, the CDC designated vaccination as first on the list of the 10 greatest public health achievements of the twentieth century.[41] In addition to smallpox eradication, the control of many common childhood infections and attendant reductions in morbidity and mortality ranked as very high achievements. Implementation of routine US childhood immunization programs led to major reductions from mid-twentieth century disease peaks to the record low levels of several infectious diseases today (Table 90.2). For example, in the United States, the number of polio, measles, rubella, and mumps cases declined by 100%, 99.9%, 99.9%, and 95.9%, respectively.[42] It is estimated that for each annual birth cohort of approximately four million children in the United States, vaccines in the childhood immunization schedule prevent an estimated 20 million cases of disease and 42 000 deaths.[43] Furthermore, although it is true that a considerable investment of resources is required to complete the annual programs of childhood vaccination, vaccines do result in very significant cost savings, and hence are highly cost-effective interventions. For each yearly US birth cohort, vaccines result in nearly $14 billion in annual net direct cost savings and $69 billion in annual net societal cost savings (which include savings such as reductions in costs of missed work by parents caring for an ill child).[43]

TABLE 90.2 **Historical Comparisons of Morbidity and Mortality for Vaccine-Preventable Diseases in the United States**

Disease	Before Vaccination: Estimated Annual Average Number of Cases	After Vaccination: Annual Cases (Reported or Estimated) in Year 2006	% Reduction
Diphtheria	21053	0	100
Measles	530217	55	99.9
Mumps	162344	6584	95.9
Pertussis	200752	15632	92.2
Paralytic poliomyelitis	16316	0	100
Rubella	47745	11	99.9
Smallpox	29005	0	100
Tetanus	580	41	92.9
Hepatitis A	117333	15296	87
Acute hepatitis B	66232	13169	80.1
Invasive Hib	20000	<50	99.8
Invasive pneumococcal disease	63067	41550	34.1
Varicella	4085120	48445	85

Hib, *Haemplhilus influenzae* type b.

(Adapted from Roush SW, Murphy TV, Vaccine-Preventable Disease Table Working Group. Historical comparisons of morbidity and mortality for vaccine-preventable diseases in the United States. JAMA 2007;298:2155–63.)

Saving lives and reducing morbidity and human suffering is the major accomplishment of vaccination. Although there are many human infectious diseases yet to be controlled by vaccination (some are discussed below), the accomplishments to date are truly spectacular. For example, the CDC estimates that US childhood vaccination programs will prevent 21 million hospitalizations and 732 000 deaths among children born in the last 20 years.[44]

Vaccines are not given solely to protect individuals against diseases. Another purpose of vaccination is to protect communities by reducing transmission of disease-causing microbes from vaccinated persons to unvaccinated persons. The term for this protection is *herd immunity* or *community immunity.*[45] A disease that has been studied closely with regard to community immunity is measles. Measles is very highly contagious and its epidemic form is easily recognizable. Clustering of poor vaccination coverage often occurs in particular communities, and this was highlighted in recent measles outbreaks in the United States.[46]

In a measles outbreak in California in 2014–2015, of the 110 patients, 49 were unvaccinated; in that subgroup, 24% were children too young to be vaccinated, and 67% were intentionally unvaccinated (mostly children) as a result of parental beliefs. Such outbreaks point out the importance of community immunity to protect the vulnerable (unvaccinated) members of our communities. Given that many of the recent measles outbreaks in the United States have been linked to imported cases, another important lesson is that as long as a vaccine-preventable, highly transmissible infectious disease exists anywhere in the world, it remains a potential threat everywhere—and thus vaccination programs will continue to be important to ensure the health of all community members in any part of the world.

Another powerful example of vaccine-induced community immunity comes from pneumococcal vaccines. There are many specific challenges associated with pneumococcal vaccines: the large number of circulating serotypes, the suboptimal immunogenicity of polysaccharide only vaccines, and noninvasive carriage of the organism—all of which lead to significant problems in establishing community immunity. However, in spite of those challenges, introduction of the pneumococcal conjugate vaccines in infants in 2000 not only led to reduction in invasive diseases among the vaccinated population of children but also produced a significant reduction in adults, particularly among seniors, in whom this bacterium frequently causes pneumonia.[1] This result highlights the effectiveness of community immunity produced by vaccines.

Other recently introduced vaccines have made a significant impact in relatively brief periods. The 2006 implementation of routine rotavirus vaccination prevents an estimated 40 000 to 60 000 rotavirus hospitalizations in the United States annually.[47] The human papillomavirus (HPV) vaccine is a recombinant virus-like particle (VLP) vaccine for primary prevention of cancer. The CDC Advisory Committee on Immunization Practices (ACIP) recommended routine HPV vaccination for girls in 2006 and for boys in 2011. Within 6 years of the introduction of vaccine for girls, there was a 64% decrease in the prevalence of the four types of HPV contained in the vaccine among females 14–19 years of age and a 34% decrease among those 20–24 years of age.[48] This example shows the power of an excellent new-generation viral vaccine, even when uptake is incomplete. At the end of the first decade of the current century, cases of hepatitis A, hepatitis B, and varicella have been reported to be at record low levels[49,50] (see Table 90.2).

RECENT CHANGES IN VACCINE DEVELOPMENT STRATEGIES

Vaccines were originally developed with no knowledge of the immunological correlates of protection or, indeed, of the existence of the immune system. Similarly, the earliest vaccines were developed without an in-depth understanding of microbial antigens and epitopes, which are critical to the production of protection against disease. Rather than having a theoretical or purely logical basis, for a century and a half after Jenner, vaccination continued to be based on experience and clinical observation. The observations and experiences led to a concept that was evaluated by a trial-and-error approach. The desired outcomes of the trial-and-error, or empirical, approach to vaccine development were protection against disease and survival after exposure to the pathogen. Vaccines were initially attenuated or killed versions of the whole wild-type human pathogens (*e.g.,* rabies, yellow fever, and influenza viruses). In a few cases, attenuated zoonotic organisms closely related to human pathogens were employed to produce cross-reactive protective responses in humans (*e.g.,* vaccinia, an animal poxvirus utilized as a vaccine against human smallpox, and Bacille Calmette-Guérin [BCG], an agent of bovine tuberculosis [TB] developed as a human TB vaccine).

Later, split-virus vaccines utilized partially purified protein antigens derived from whole killed viruses (*e.g.,* split-virus influenza vaccines). The polysaccharide capsules of bacteria were purified from cultures of serologically distinguishable strains, or serotypes, within single bacterial species leading to polyvalent polysaccharide vaccines (*e.g.,* the 23-valent pneumococcal polysaccharide and the quadrivalent meningococcal polysaccharide vaccine). Bacterial toxins were purified from cultures and made harmless by application of heat or chemical treatment to produce toxoid vaccines (*e.g.,* tetanus and diphtheria vaccines).

During the closing years of the twentieth century and in the early twenty-first century, the advances in genetics, molecular biology, immunology, and microbiology have led to new theory-based (so-called rational) approaches to vaccine development. Perhaps "informed empiricism" is an apt description of much of early twenty-first century vaccine development: experimental approaches that are heavily influenced by our now-imperfect, always evolving knowledge of innate and adaptive immune responses and of microbial antigens but are still dependent on an iterative system of trial and error to discover safe, well-tolerated, and efficacious vaccines. Vaccine developers today also benefit from the cumulative body of knowledge and experience in vaccinology that has accumulated over the past century.

There have been numerous changes in the design of vaccine immunogens. The formation of links between bacterial polysaccharides and protein carriers (*conjugation*) led to dramatic improvements in protection against certain bacterial diseases. Conjugation of *H. influenzae, N. meningitidis,* and, most recently, *S. pneumoniae* polysaccharides to proteins improved these vaccines by converting them from T cell–independent antigens to T cell–dependent antigens.

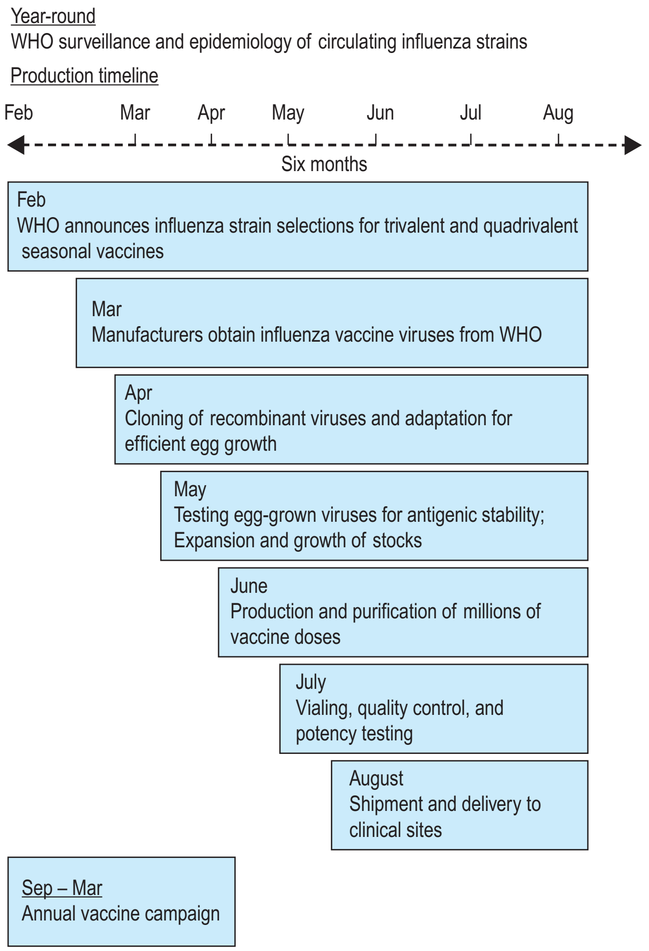
Adjuvants are materials added to vaccine antigens to enhance the recipient's immune response. Recent advances in our understanding of the innate immune system have led to an appreciation that adjuvants act through their effects on innate immunity. Adjuvant-triggered innate signals enhance the quantity and quality of the downstream adaptive immune responses to the vaccine antigen. Today's vaccinologists are developing vaccines with specific molecular adjuvants (*e.g.,* Toll-like receptor-5 [TLR-5], CD-40L, and interleukin-12 [IL-12]), intended to shape the immune response to provide a presumed best fit for protective immunity against the targeted pathogen.

The advent of molecular biology in the mid-twentieth century resulted in many new avenues for vaccine development. Advances in molecular biology allowed for cloning of microbes' genes and their expression in recombinant molecular systems, and vaccines could consequently be designed on the basis of the *in vitro* expression of one or a few genes. For example, the hepatitis B vaccine, originally developed by Hilleman, was purified hepatitis B surface antigen (HBsAg) from the blood of humans with chronic infection. Soon thereafter, a second licensed hepatitis B vaccine was produced in yeast cells through recombinant DNA methods that inserted the HBsAg gene into yeast organisms for expression and purification. The recombinant hepatitis B vaccine is in use in the United States and offers advantages, such as protein purity (because the genes-of-interest are expressed in relative isolation) and vaccine safety (because it is no longer necessary to derive vaccines by partially purifying the HBsAg from paid-donor plasma of humans chronically infected with hepatitis B virus and potentially other viruses).

Another example of a highly effective recombinant vaccine is the HPV vaccine. Recombinant HPV L proteins expressed in recombinant systems form VLPs that are purified and formulated with or without an adjuvant. The most recent polyvalent vaccine expresses VLPs representing nine HPV serotypes. HPV vaccines are truly remarkable for their efficacy and safety and because they offer primary prevention against several types of cancer in both females and males.

It is notable that several countries have recently licensed the first dengue vaccine.[51] It is a recombinant live viral vector that is based on the yellow fever virus vaccine strain 17D but in which the E and preM genes of 17D have been replaced by the E and preM genes of dengue serotypes 1, 2, 3, and 4. Four separate recombinant vectors were developed, one for each of the four dengue serotypes. The fact that the dengue virus and yellow fever virus are both flaviviruses with similar genetic organization facilitated development of this chimeric yellow fever–dengue vaccine. The final formulation is a tetravalent mixture of recombinant viruses representing all four dengue serotypes.

Over the last decade, systems biology, or systems vaccinology, approaches to vaccine development have captured considerable interest.[52-55] The use of new high-throughput assays to assess multiple dimensions of innate and adaptive immune responses has generated very large data sets. In addition to the traditional cellular and humoral immunological assays (antibodies, T cells, B cells), multiple "-omics" assays, including transcriptomics, proteomics, metabolomics, lipidomics, and glycomics, among others, may be performed. These detailed assessments are being applied in a variety of infectious and noninfectious disease states. One advantage for vaccine systems biology studies that enroll generally healthy study participants is the ability to obtain one or more baseline, preperturbation (prevaccination) sets of samples for analysis. Postvaccination changes can therefore be compared with the undisturbed condition. Analyses and integration of the huge amounts of collected data require multidisciplinary collaboration with computational biologists and informaticians. One application of the systems vaccine approach is to dissect the "-omics" responses produced by protective vaccines to identify associated changes at the RNA, protein, metabolite, lipid, and/or glycans levels. The promise, and some might say "hype," of systems vaccinology is both exciting and unfulfilled—and will be realized once actual improvements in human health have been achieved as a result of the systems approach.



WHO surveillance and epidemiology of circulating influenza strains

Annual vaccine campaign

FIG 90.2 **An Approximation of the Current Annual Influenza Vaccine Production Process for the Northern Hemisphere.** This is the process for egg-based vaccine production. A few manufacturers' recombinant vaccine techniques have recently eased the tight annual timeline, but most vaccines remain egg based. Development of a universal vaccine would obviate this challenging and time-constrained annual process.

CURRENT RECOMMENDATIONS

Currently in the United States, clear guidelines recommend vaccines for children, adolescents, and adults. Each February, the CDC publishes two immunization schedules[56] based on the recommendations of the CDC's Advisory Committee on Immunization Practices (ACIP). One ACIP schedule of immunizations provides the adult immunization recommendations[57] (Fig. 90.3). The adult schedule has recommendations for each vaccine based on the age of the patient. For example, the ACIP recommends that all adults (persons ≥19 years of age) receive annual influenza vaccination; a tetanus–diphtheria–acellular pertussis (Tdap) vaccine once, followed by tetanus boosters every 10 years; zoster vaccination at age 60 years; and pneumococcal vaccination at age 65 years. It should be noted that although the US Food and Drug Administration (FDA) has licensed a zoster vaccine for use at age 50 years, the ACIP recommendations do not always align completely with FDA indications (hence the ACIP recommendation for the zoster vaccine at age 60 years).

The adult schedule also provides recommendations for vaccines indicated for certain risk factors, including medical conditions (*e.g.*, immunocompromising conditions, kidney failure, diabetes) or life style, occupational, or other conditions (*e.g.*, pregnancy, men who have sex with men, health care personnel). Live vaccines (varicella, zoster, and MMR) are contraindicated in pregnant women, immunocompromised hosts, and those with human immunodeficiency virus (HIV) infection when the CD4 T-cell absolute count is below 200 cells/μL.

The second ACIP immunization schedule of immunizations covers the period from birth to 18 years and includes recommendations for children or adolescents who have not received recommended vaccines[58] (Fig. 90.4). The ministries of health in many European countries publish their own country-specific immunization schedules, and vaccination guidelines that are published by the WHO are utilized by many developing countries. The schedules are generally similar but with some region-specific differences. For example, the 2016 US ACIP immunization schedule for children recommends vaccinations against 10 viral diseases: hepatitis B, rotavirus infection, polio, influenza, measles, mumps, rubella, varicella, hepatitis A, and HPV infection.[58] Preventive viral vaccines in the WHO-recommended routine immunization schedule for children include the same 10 viral vaccines (although four of those, mumps, influenza, varicella, and hepatitis A vaccines, are recommended only for country-specific immunization programs with certain characteristics). The WHO schedule also recommends some additional vaccines (*e.g.*, rabies, yellow fever, Japanese encephalitis, and tick-borne encephalitis vaccines are recommended for certain high-risk populations).[59]

SOME PRESENT AND FUTURE CHALLENGES

The science of vaccinology is exciting and strong, having entered a new era with the high-throughput analytical and data approaches being applied today. Whether these advances in technology, computation, and science will result in improvements in human health remains to be seen. At present there is some (healthy) skepticism about the big data systems biology approach. The field must show that the massive data can be analyzed and integrated and that the approach is more than a fishing expedition but, rather, is an exploratory engine that is hypothesis generating and also leads to models that will be tested and will produce new knowledge, resulting in improved vaccines that benefit human health.

For outstanding scientists to be attracted to and retained in the field of vaccinology, it is essential that science funding agencies provide and maintain robust support for critical discovery research projects (investigator-initiated research projects) that form the engine of innovation that drives all of science. At the same time, targeted big science vaccine program projects and networks have the potential to synergistically pool their approaches in an intense focused effort to tackle major vaccine needs and challenges (*e.g.*, development of HIV and TB vaccines). To translate basic advances and laboratory science into improved health care for patients, having well-trained translational physician-scientists lead clinical–translational human research programs is an additional component of essential infrastructure. There is a need for postdoctoral training programs that focus on vaccinology, but

only a few are in existence. The future of the field depends on attracting and training a next generation of highly qualified vaccinology research leaders.

Patients' and parents' confidence in and uptake of vaccines derives most of all from the advice and education provided by their trusted physicians and other clinicians. But because of the high time pressures of office or hospital encounters, clinicians often find it challenging to prioritize patient education about vaccination. Nonetheless the clinician–patient encounter is the most potent opportunity for education and influence, and this opportunity must be seized for vaccine programs to be successful. Every physician/clinician encounter is an opportunity to review vaccination history, recommend and discuss needed vaccines, and bring our patients' vaccinations up to date.

Training of health care professionals and education of the public are essential dimensions for vaccination to achieve its potential as a driver of improved health. Clearly a vaccine that stays in its vial has no use at all. Health care providers must be inspired and trained to serve as advocates and champions of vaccination; to remember to discuss vaccination at every patient encounter; to stock vaccines in their refrigerators and freezers; and to use electronic reminder systems to ensure compliance with recommended vaccinations based on the patient's age and medical or other indications.

Public awareness and education about vaccination must be enhanced through professional marketing campaigns. The negative consequences of propaganda by antivaccination groups, alternative or delayed schedules of vaccination, and parental hesitancy regarding vaccination can all result in resurgence of infectious diseases, increased morbidity, and increased vaccine-preventable deaths.

With modern air travel, which makes it possible to go from one continent to another in a matter of a few hours, it is no stretch to say we dwell in a global village, where maintaining good health and avoiding highly contagious infectious diseases depend on the health of communities, whether local or global. Therefore it is in our self-interest to maintain high levels of vaccination in our home communities and to advocate and support vaccination efforts around the globe. Clearly, vaccination is both a personal and a social, or community, endeavor.

A few specific challenges for vaccination are highlighted below to illustrate the general points made above.

A Vaccine Against Human Immunodeficiency Virus

The development of a vaccine against human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) has long been recognized as a top HIV research global priority at the US National Institutes of Health (NIH). Strong and simple treatments for those who are living with HIV infection are now in existence in the United States and have been made available even in developing countries. It has been shown that the treatment-as-prevention approach, wherein the viral load is lowered to an undetectable level by antiretroviral treatment of infected persons, results not only in benefit to the infected patient but also in up to 96% reduction in HIV incidence among sexual partners.[60,61]

More recently, antiretroviral drugs (ARDs) have been tested globally and licensed in the United States as a once-daily pill (a combination of tenofovir and emtricitabine) for HIV/AIDS prevention in higher-risk individuals.[62] Known as *preexposure*

prophylaxis (PrEP), this approach, in an ideal setting with unlimited resources and complete patient compliance, could have a truly dramatic impact on HIV incidence. However, to date, uptake has been low, and patient adherence to treatment continues to be a concern. Many of those most at risk for HIV infection do not have medical insurance and cannot afford to purchase medications.

Although the advances in HIV treatment, treatment-as-prevention, and PrEP have been significant, the numbers of new infections globally remain unacceptably high, with 2.1 million new infections reported in 2015 and a total of 36.7 million people living with HIV infection.[63] In the United States, progress on the prevention of HIV infections through the use of condoms, education, and evidence-based interventions has plateaued at ≈44 000 new infections annually. Another remarkable achievement of ARDs has been the dramatic reduction in AIDS-related deaths in the United States, from a peak of ≈55 000 per year to ≈13 000 per year. As a consequence of the unabated incidence of HIV infection and the reduced mortality, the number of people living with HIV in the United States is now increasing at a rate of ≈30 000 per year.

The global need for an HIV vaccine remains strong. However, there are large scientific challenges, and despite more than 30 years of major efforts since the identification of the viral etiological agent of AIDS in 1984, a licensed HIV vaccine with proven protective efficacy continues to be elusive. The field has completed (only) five efficacy trials, which did not achieve protection in vaccinated higher-risk subjects relative to placebo recipients,[64-68] and in two of the trials (which tested replication-deficient adenovirus serotype 5 recombinant vaccine vectors expressing HIV Gag, Pol, and Nef but not Env), there were reports of higher rates of HIV infection in some subsets of participants in the vaccine groups compared with the placebo groups.[69,70]

Importantly, modest vaccine efficacy was observed in a sixth efficacy trial reported in 2009.[71] This 16 000-person study, known as RV144, which was conducted by the US Army in collaboration with the government of Thailand, evaluated a prime-boost regimen of a nonreplicating canarypox vector prime (expressing HIV Gag, protease and gp120) followed by boosting with the same vector plus a bivalent gp120 protein adjuvanted in alum. To the surprise of some early critics of the trial and many in the field, the RV144 regimen produced modest (31.2%) protection in the general population of Thailand at 3.5 years after vaccination, and 61% protection in the first year after vaccination.[71]

This first evidence of human protection provided by an HIV vaccine proved that development of an HIV vaccine would be possible, and this has significantly reenergized the field. In follow-up laboratory studies, an NIH-funded international collaborative program that assessed the immunological correlates of RV144 infection risk revealed that the level of nonneutralizing immunoglobulin G (IgG) antibody targeting a V1V2 loop antigen from the HIV Env gp120 protein correlated inversely with risk of infection, whereas the level of IgA antibody against gp120 protein directly correlated with infection.[72] The IgG antibody was capable of mediating antibody-dependent cellular cytotoxicity (ADCC), whereas the IgA antibody competed with IgG for binding to gp120 V2.[72] The US National Institute of Allergy and Infectious Diseases (NIAID)—funded HIV Vaccine Trials Network (HVTN), the US Army, and country level and industry collaborators have formed the Pox-Protein Public-Private Partnership (also known as "P5") to plan an intensive series of follow-up human studies to confirm and fully investigate the important leads provided to the field by RV144.[73] Efficacy trials that will test next-generation HIV vaccine regimens of clade C–expressing poxvirus vectors with adjuvanted protein boosts and may include DNA vector priming are being planned for southern Africa. In that region, the HIV clade C (the most prevalent global clade) predominates, and the population has a higher risk of HIV acquisition compared with Thailand, where the clades E and B predominate. The coming decade in HIV vaccine research will be highly interesting. Will the "improved versions" of the RV144 regimen provide protection in southern Africa among the higher-risk, genetically distinct population of Africans exposed to C clade HIV?

Discovery of a vaccine immunogen that induces broadly neutralizing antibodies remains the holy grail of HIV vaccination. Such antibodies do occur naturally in up to 15% of chronically infected persons, but only after years of infection. Although seen in natural infection, no vaccine has been able to induce these broadly neutralizing antibodies in vaccinated humans. However, several broadly neutralizing monoclonal antibodies (mAbs) have been cloned, and a few have been tested for safety and pharmacokinetics in early-phase human trials. The antibody genes are highly mutated from their germline with ≈20–25% mutations, indicating that extensive somatic hypermutation (SHM) has occurred in the lymph-node germinal centers (GCs). They also tend to have short complementarity-determining region 1 (CDR1) arms and as a result of autoreactivity against self lipids, these clones are frequently deleted.[74]

The NIAID, through two of its HIV/AIDS clinical trials networks (the HVTN and the HIV Prevention Trials Network [HPTN]), is conducting a phase IIB efficacy trial of VRC01, one of the broadly neutralizing mAbs. In laboratory virus neutralization assays, this antibody has activity against >90% of 343 strains of HIV-1 across all clades at an IC80 of <1 μg/mL.[75,76] The ongoing VRC01 efficacy trial (or the antibody-mediated protection [AMP] study) is a randomized, double-blind, placebo-controlled clinical trial, where the antibody will be infused intravenously every other month for 18 months at doses of 0 mg/kg (placebo), 15 mg/kg, or 30 mg/kg. If the VRC01 antibody does protect at-risk humans against HIV acquisition, this will provide a clear impetus to the HIV vaccine field to continue and intensify efforts to develop immunogens capable of inducing similar or further improved broadly neutralizing antibodies. Notably, the preparation used in the VRC01 trial is a single antibody, and many experts feel that a combination of mAbs targeting different epitopes on the gp120 envelope protein structure may provide an even stronger result. The AMP study result is eagerly awaited.

Improved Influenza Vaccines

Seasonal influenza A imposes a significant disease burden, with the highest morbidity occurring in children and the highest mortality occurring in persons over 65 years of age. The CDC estimates that in the United States, annually influenza is responsible for 200 000 hospitalizations in infants and children and 3000 to 49 000 deaths (depending on the year), with 90% occurring in seniors. Influenza case numbers peak in February during most years, and 10% of the population can become infected in a season. In the United States, starting from 2010, it is recommended that all persons ≥6 months of age receive an annual influenza vaccine. If fully implemented, this would entail administration of 350 million doses each year.

There are two types of influenza, A and B, responsible for most human disease, and multiple subtypes of influenza A, which are categorized on the basis of the amino acid (AA) sequence homology within the HA and NA proteins. Currently 19 HA and nine NA subtypes are recognized, and these can combine to form many viral subtypes (*e.g.,* H1N1, H3N2, H5N1), which are further defined as specific strains based on AA sequence. Influenza B is further categorized into two lineages, Yamagata and Victoria.

Influenza is a negative-stranded RNA virus that lacks a proofreading function in its viral polymerase; hence it is highly mutable. One of the truisms about influenza is that the only thing predictable about influenza is that it is unpredictable. Because of the RNA genome mutations that continually accumulate during influenza replication, the WHO issues a recommendation every February for a new vaccine strain composition. Vaccine manufacturers in the Northern Hemisphere then race to produce the year's trivalent or quadrivalent seasonal vaccine by late summer to be ready for the winter influenza season. There are multiple challenges and needs with regard to this repeated (endless) annual process of influenza vaccine prediction, production, distribution, implementation, uptake, and protection (Fig. 90.2).

For the segment of the population that has the highest mortality, that is, older adults, currently available vaccines provide only relatively weak protection against influenza diagnosed with polymerase chain reaction (PCR). One approach to this challenge has been vaccination of persons ≥65 years of age with a fourfold higher dose of antigen, 60 μg (rather than 15 μg) for each strain based on HA protein content. This high-dose vaccine was shown to increase both immunogenicity (ref) and efficacy and was licensed for use in seniors in the United States.[11,12]

In European and many other countries, for a number of years, an oil-in-water adjuvant, MF59, has been licensed for use in influenza vaccine formulations specifically for seniors. The tolerability and safety of this adjuvanted vaccine has been demonstrated in tens of millions of recipients, and the increases in immune response and efficacy are well documented.[13] In 2015, on the basis of safety and antibody response data from clinical trials, the US FDA approved this oil-in-water adjuvant, designated as MF59, in a formulation of an influenza vaccine for use in seniors.[14] Therefore for seasonal influenza vaccination of seniors in the United States, clinicians will now, as in many other countries, have an adjuvanted influenza vaccine option that provides enhanced immunogenicity.

Another approach to increased protection of seniors against mortality caused by is better community (herd) immunity. The CDC's ACIP recommendation for universal influenza vaccination of all persons >6 months of age has the potential to reduce mortality in seniors, even when a senior citizen's antibody level remains suboptimal after vaccination. If nearly everyone around a senior citizen is vaccinated and protected, a susceptible senior would be much less likely to come in contact with the influenza virus. Enhancing uptake of the annual vaccine by all children and adults is thus an effective approach to improving protection of the vulnerable population of seniors.

Seasonal influenza vaccine effectiveness varies year to year for each influenza A subtype or influenza B lineage, depending on the degree of match between the vaccine strains and the circulating strains. To allow vaccine manufacturers the 6 months currently required for egg-based vaccine production methods, the vaccine strains for each subtype and lineage must currently be selected in February for the following season's vaccine campaign. The burden of annual revaccination of the entire population against a variable viral target is high, both logistically and financially. Furthermore, uptake of the annual seasonal influenza vaccine in the general population remains suboptimal. Over the past decade, considerable effort has been put into the development of the so-called universal influenza vaccine. The universal vaccine would target conserved regions on the HA protein (*e.g.,* the highly conserved stalk rather than the hypervariable head) or other conserved viral proteins (*e.g.,* the M protein). Some of the universal influenza vaccine candidates are moving into early-phase human safety and immunogenicity clinical trials. If a safe and effective universal influenza vaccine can be developed, the goal would be to replace annual revaccination against the current season's strains with initial vaccination and periodic boosting with a universal vaccine that should protect against any influenza variant that arises each year (*e.g.,* a booster every decade as for tetanus). A further advantage would be pandemic preparedness and prevention because the universal influenza vaccine, by targeting conserved viral domains present on all viruses, should also protect against avian strains, such as A/H5N1 or A/H7N9.[77,78] Finally, recent studies comparing a standard-dose conventional (egg-produced) quadrivalent vaccine to a recombinant quadrivalent HA protein vaccine produced by a cell-line in serum-free medium demonstrated better protection in older adults with the recombinant than the conventional vaccine, thus suggesting the possibility of a newer chapter in vaccine production.[78a]

Zika Virus

A current challenge that also encapsulates the recent history of pathogens reemerging and spreading globally from continent to continent is the ongoing Zika virus epidemic. Zika virus is a reemerging flavivirus closely related to dengue virus. As of 2015, this single-stranded positive-sense RNA virus has been causing an epidemic of mosquito-borne dengue-like illness across South and Central Americas and the Caribbean. Infections in pregnant women, with resulting fetal microcephaly or other birth anomalies, are the most feared and serious consequences of Zika virus infection.[7] A mosquito-borne viral cause of birth defects has never existed before. In general, healthy adults with symptomatic infections experience a mild to moderate self-limiting viral illness that has been described as "mild dengue" and is mostly characterized by fever, rash, conjunctivitis, and arthritis. An increased association of Guillain-Barré syndrome (GBS) with Zika virus infection has been reported in multiple countries, and research is ongoing to determine if a causal relationship exists. Interestingly, it is believed that 80% of Zika virus infections are asymptomatic. In symptomatic infected adults, viremia persists for less than a week in most cases, but longer durations of viral RNA detection are reported in semen and urine.[79,80]

In summer 2016, most Zika virus infections in the continental United States were diagnosed in travelers who returned from Zika virus epidemic areas in Latin America or in their sexual contacts. However, a few cases of local transmission had occurred by midsummer 2016 in southern United States. These southernmost parts of the country will likely experience ongoing limited local transmissions as a result of the broad susceptibility of the population and the presence of the primary mosquito vector *Aedes aegypti.* The projection for only limited local transmission in the United States is based on recent prior experiences with dengue and chikungunya, which are also spread by the same mosquito vector. However, the risk and magnitude of harm that will occur in the United States because of this emerging virus is truly unknown.

Although the virus was first identified nearly 70 years earlier in 1947 in the Zika forest in Uganda, only rare human infections had been documented in Africa and Asia for 60 years. Relatively little scientific work was conducted. Then in 2007, a Zika virus outbreak occurred in the Yap Islands in Micronesia,[81] and in 2013, there was an outbreak in French Polynesia.[82] By 2015, large numbers of persons in Brazil were becoming infected, and in 2016, the virus continued to spread across the Americas and the Caribbean islands. Associations of the Zika virus with increased incidences of microcephaly in newborns and GBS in adults led the WHO to declare a "Global Public Health Emergency of International Concern" on February 1, 2016. Several governments in the affected regions have advised women to delay pregnancy. No vaccine or treatment is currently available.

As a response to the Zika virus epidemic, the development of a vaccine has emerged as a top priority of the US government. Preclinical work has demonstrated efficacy and human vaccine trials are on-going. A WHO website indicates that over 15 pharmaceutical and governmental entities are working on finding a Zika virus vaccine.

The vaccine field has a sense of optimism that a Zika virus vaccine can be developed relatively quickly, given that there are several existing flavivirus vaccines in use around the world. The live attenuated yellow fever virus vaccine 17D, developed by Theiler, has been extensively used since 1927. Chimeric yellow fever virus 17D–dengue virus vaccines have been licensed in several countries, and a live attenuated dengue vaccine was recently shown to be protective in a human challenge study.[21,51] Furthermore, tickborne encephalitis virus vaccines have been in use for decades in Russia and Europe, and a West Nile virus vaccine that expresses viral antigens from a DNA vector was developed by the NIAID and was shown to have acceptable safety and promising immunogenicity in humans.

Other Needed Vaccines

It is beyond the scope of this chapter to describe in detail all the new or improved vaccines that are needed to address significant infectious disease burdens. Brief mention is given to a few more needed vaccines that have been reviewed elsewhere recently.

The Ebola epidemic of 2014–2015 highlighted the importance of having a vaccine ready for the next inevitable outbreak of that recurrent periodic killer disease. Major field trials of candidate Ebola vaccines were launched in 2015, but before the major efficacy endpoints were achieved, the epidemic waned. However, a preliminary result of strong efficacy for the recombinant vesicular stomatitis virus (rVSV)–Ebola glycoprotein vaccine was

ON THE HORIZON

- As valuable as vaccines have been in improving health in the past century, they are likely to be even more valuable in the next century.
- Emerging infections capable of severe morbidity (*e.g.,* Zika virus) or mortality (*e.g.,* Ebola virus and avian influenza virus A/H7N9) continue to emerge and threaten global human health with alarming regularity.
- Having rapid vaccine platforms "on the shelf"—to enable quick production, preclinical testing and human safety, immunogenicity and efficacy testing—is critical to timely and effective responses to outbreaks that may spread globally very rapidly as a result of international air travel.
- Several older technologies for vaccine production (*e.g.,* egg-based production of influenza antigens) or immune response assessment (*e.g.,* hemagglutination inhibition assays) will be replaced by newer, improved methods (*e.g.,* cell culture–derived recombinant antigens and automated high-throughput neutralization assays).
- There will be increased application of new molecular adjuvants (*e.g.,* CD40L, Toll-like receptor-5 [TLR-5], or interleukin-12 [IL-12]) that target specific biochemical pathways to direct and shape the cascade from innate immune response to desired adaptive immunity protective response.
- The worsening problem of antibacterial resistance is inspiring new efforts to prevent morbidity and mortality resulting from multidrug-resistant, hospital-acquired infections through vaccination—that is, it is better to prevent an infection caused by a highly resistant microbe than to try to treat it.

obtained in Guinea, where the epidemic persisted somewhat longer than it did in Sierra Leone or Liberia.[83,84] Even though the progression of candidate Ebola vaccines to field trials was rapid (and impressive), the experience with the timing of the availability of the Ebola vaccine for efficacy testing and field use versus the waning arc of the Ebola epidemic points to a recurring concern. This same concern also arose during the 2009 influenza A pandemic—namely, when major epidemics of highly infectious and lethal infectious diseases occur, can protective vaccines be developed quickly enough to have an impact and save lives? Some who have raised this concern have suggested that one solution is to prepare a library and/or repository of vaccines or platforms for all possible epidemic pathogens in advance so as to ensure readiness.

A major international effort to develop a malaria vaccine has been ongoing for many years, and recent efficacy trials have produced encouraging results.[85,86]

Along with HIV/AIDS and malaria, TB is one of the three top infectious killers each year and remains a major target for development of a vaccine to reduce mortality and morbidity.[87-89]

In the past decade, *Bordetella pertussis* infection, or whooping cough, cases in the United States have increased to levels not observed since the 1950s. The transition from the previously used whole-cell pertussis vaccine to the current acellular pertussis vaccine is thought to be responsible. Although the older vaccine was more reactogenic, it was also more protective. Pertussis vaccine developers and public health officials are working to develop new vaccines and to determine the correlates of protective efficacy and are considering the best options to reduce the incidence of pertussis.[90]

MULTIPLE-CHOICE QUESTIONS

1. The physician often recognized as the "father of vaccinology" is:
   A. James Phipps
   B. Robert Koch
   C. Edward Jenner
   D. Louis Pasteur

2. The polysaccharide vaccines developed for the prevention of bacterial diseases caused by pathogenic organisms, such as *Haemophilus influenzae, Neisseria meningitidis,* and *Streptococcus pneumoniae,* became much more useful upon conjugation with:
   A. Lipids
   B. Small molecule metabolites
   C. Proteins
   D. Polymers

3. The Advisory Committee on Immunization Practices (ACIP) of the US Centers for Disease Control and Prevention (CDC) in its adult immunization schedule makes annual recommendations for each vaccine based on the age of the patient, and other indications. In the 2017 schedule, these included:
   A. All adults (persons ≥19 years of age) should receive annual influenza vaccination; a tetanus–diphtheria–acellular pertussis (Tdap) vaccine once, followed by tetanus boosters every 10 years; zoster vaccination at 60 years of age; and pneumococcal vaccination at 65 years of age.
   B. Other vaccines indicated for certain risk factors, including medical conditions (*e.g.*, immunocompromising conditions, kidney failure, diabetes) or life style, occupational, or other conditions (*e.g.*, pregnancy, men who have sex with men, health care personnel).
   C. Live vaccines (varicella, zoster, and measles–mumps–rubella [MMR]) are contraindicated for pregnant women, immunocompromised hosts, and in those with human immunodeficiency virus [HIV] infection when the CD4+ T-cell absolute count is below 200 cells/μL.
   D. All of the above are correct.

91

Immunotherapy of Allergic Disease

Anthony J. Frew

Specific-allergen immunotherapy (SIT), or allergen desensitization, is used to treat various forms of allergic disease that involve type I hypersensitivity. SIT involves the administration of allergen extracts to modify or abolish symptoms associated with exposure to relevant allergens. SIT is used for three distinct types of allergic condition: anaphylaxis, rhinoconjunctivitis, and asthma. In anaphylaxis, the patient is completely well between episodes; exposure is infrequent and unexpected but provokes an immediate and potentially catastrophic response. However, since exposure only occurs occasionally, it can be difficult to know whether the treatment has been effective until an accidental exposure event occurs. Allergic rhinoconjunctivitis is clearly driven by allergen exposure, which is low level and may be either continuous or intermittent. Exposure and clinical relevance are most obvious for seasonal rhinitis (caused by pollens or molds), occupational rhinitis, and for rhinitis caused by animal danders. Because there is no seasonal variation in perennial rhinitis, it is more difficult to be sure that allergen exposure drives symptoms—in some cases it clearly does, but in others there may be nonallergic or structural causes for the symptoms. The value of SIT for rhinoconjunctivitis is generally clearer when exposure is predictable, but assessing efficacy is complicated by year-to-year variations in pollen exposure because of weather patterns and individual activity. The third indication for SIT is asthma, where the role of allergen exposure is different from that in rhinoconjunctivitis. As discussed elsewhere, allergen sensitization is a risk factor for developing asthma in childhood, but it is less clear whether allergen exposure has a role in ongoing asthma. At the very least, the fact that allergen avoidance measures are not usually effective in asthma begs the question whether modifying the response to allergen will influence established disease. It is inherently more risky to use SIT to treat patients with asthma compared with treating those who do not have asthma, so the benefits and risks must be weighed carefully when considering the use of SIT to treat patients with asthma.

The general principles of managing any allergic condition are to make an accurate diagnosis, identify relevant trigger factors, institute appropriate interventions to reduce the impact of those triggers, and control symptoms and disease progression. Allergen avoidance measures may help but are rarely sufficient to avoid the need for other therapies. Drug treatments can be very effective, but they only work as long as the drugs are taken. SIT is the only current therapy that modifies the immune response to allergens. It is specific in that treatment is targeted at those allergens recognized by the patient and physician as responsible for symptoms. Although claims have been made for bystander benefits on unrelated allergens, there is little convincing evidence that SIT for one allergy can alleviate symptoms caused by different allergens. Before deciding to use SIT, it is, therefore, essential to assess the patient's condition carefully, especially the role of allergic triggers.

SIT was pioneered over 100 years ago and developed as an empirical science of pollen vaccination, based on the mistaken concept that hay fever was caused by infection.[1] Early studies found that giving large doses of pollen would trigger allergic reactions, so regimes that start with extremely low doses and build up to a maintenance dose that is given every few weeks were developed. A great deal has been learned about the immunological events associated with clinically successful SIT, but uncertainties remain about which of these events is truly important in delivering the clinical benefit. New and modified forms of SIT have been developed to deliver these immunological effects more efficiently, but none of these, as yet, has the efficacy of the standard approach.

Following initial reports from the United Kingdom, SIT was developed in the 1920s–30s in North America, where some differences in practice emerged compared with European practice. In particular, American allergists tend to treat patients for all sensitivities identified on skin testing, using personalized mixtures of extracts prepared from bulk vials, whereas in Europe, patients are normally treated with single allergens, which are supplied directly by the manufacturer. However, pollens from different grasses or trees are often combined. Mixtures of allergens from different sources (*e.g.,* mites and pollens) are used in some parts of Europe as custom mixes from manufacturers. Different approaches are also taken for standardization of extracts. Allergen extracts used in Europe are standardized by their ability to elicit a weal, whereas US standardization has been based on erythema rather than weal.

Whichever form of extract is chosen, patients are started on a very low dose of allergen, and the dose is then increased, usually at weekly intervals, until reaching the maintenance dose, which is then given at 4- to 6-weekly intervals for 3–5 years. Alternative induction protocols may involve several doses on each day (semirush), or the whole series of incremental injections may be given in a single day (rush). The main drawback to rush and semirush protocols is the frequency of adverse reactions, which occur much more often than with conventional protocols. However, full protection can be attained in a few days compared with the 3 months required in the conventional regime. Normally, the doses are given by subcutaneous injection, but since 1990, there has been increasing interest in SIT administered by the sublingual route, which is more convenient for patients and has some advantages in terms of safety.

MECHANISMS OF SIT

KEY CONCEPTS

Possible Mechanisms of Immunotherapy

- Induction of immunoglobulin G (IgG) (blocking) antibodies
- Reduction in specific IgE (long-term)
- Reduced recruitment of effector cells
- Altered T-cell cytokine balance (shift to T-helper cell-1 [Th1] from Th2)
- T-cell anergy
- B-cell suppression

The primary reason for studying the mechanisms of SIT is to identify features that are biologically important and thus to devise new forms of immunotherapy that may improve efficacy, increase safety margins, shorten treatment courses, or achieve more durable results from SIT. At least three distinct phases can be identified in SIT, each with distinct immunological mechanisms.[2] Initially, there is pharmacological desensitization, in which basophils and mast cells are rendered tolerant of the allergen. This is achieved quickly, within a few days if the rush protocol is followed. Clinically, this not only allows the patient to tolerate the maintenance dose of allergen but also protects against acute exposure to allergen (*e.g.,* a wasp sting). This state of pharmacological tolerance is not permanent and rapidly disappears if SIT is stopped. During the first year of maintenance SIT, T-cell tolerance is achieved, with abrogation of late-phase responses to allergen exposure and induction of regulatory T cells (Tregs). Finally, with prolonged treatment, B-cell tolerance develops, and the level of sensitizing antibodies decreases.

Following subcutaneous injection of allergen extracts, a small proportion of the allergenic material is taken up by phagocytic cells and carried to regional lymph nodes. The process is fairly inefficient: <1% of a radiolabeled dose actually reaches the lymph nodes. Almost all studies have shown that SIT induces allergen-specific immunoglobulin G (IgG) antibodies, which increase progressively during treatment. This led to suggestions that SIT might work by inducing antibodies that intercept the allergen and "block" the allergic response. In patients treated for venom anaphylaxis, the development of allergen-specific IgG antibody correlates with clinical efficacy, but for other allergens, the magnitude of the IgG response is not closely related to the degree of efficacy. Moreover, the rise in IgG follows, rather than precedes, onset of clinical benefit. Allergen-specific IgE antibodies increase initially, but the usual seasonal rise in IgE is blunted.[3] Over several years, the amount of allergen-specific IgE declines but does not disappear. In keeping with this, there is little effect on immediate skin test responses to allergen. In contrast, the late-phase skin test response is virtually abolished after successful SIT. Similar patterns are observed for late-phase nasal and airway responses.[4]

SIT also affects allergen-specific T cells. In both skin and the nose, successful SIT is accompanied by a reduction in T-cell and eosinophil recruitment in response to allergen challenge. In parallel, the balance of T-helper cell-1 (Th1) and Th2 cytokine expression (Chapter 16) alters at allergen-challenged sites. Th2 cytokine expression is not affected, but an increased proportion of the recruited T cells express the Th1 cytokines interleukin-2 (IL-2), interferon-γ (IFN-γ), and IL-12. In addition, there is induction of allergen-specific CD4 Tregs that express CD25, FOXP3, and IL-10.[2] IL-10 is induced within a few days of starting SIT and has a number of biological effects that could explain the beneficial effects of immunotherapy. These include modulation of IL-4–induced B-cell IgE production in favor of IgG4, inhibition of IgE-dependent mast cell activation, inhibition of human eosinophil cytokine production and survival, suppression of IL-5, and induction of antigen-specific anergy (Fig. 91.1). Taken together, these findings suggest that SIT modulates allergen-specific T cells, which explains why clinical and late-phase responses are attenuated without much effect on allergen-specific antibody levels. Further work in this area is now concentrating on finding more efficient ways of inducing allergen-specific Tregs. Some caution is needed: Most of the evidence of Treg induction is from peripheral blood rather than from target organs, and although

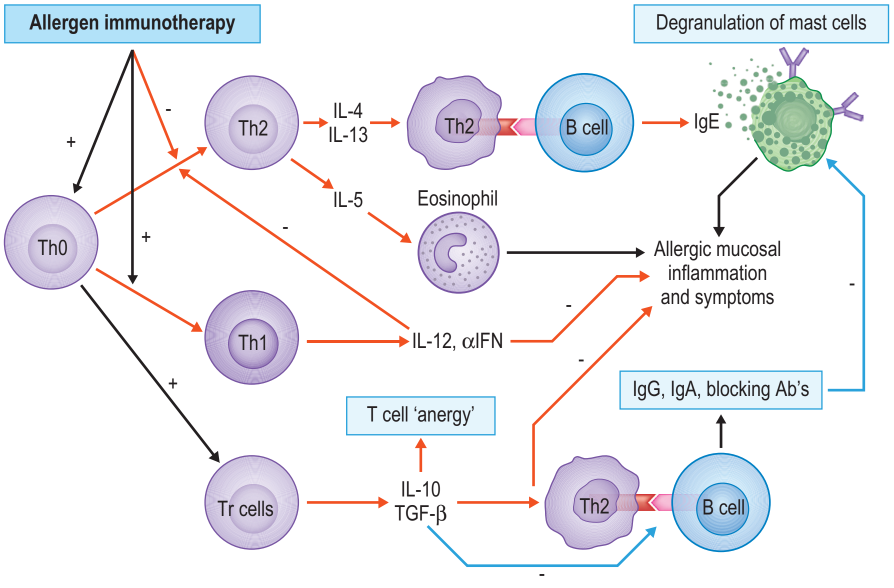

FIG 91.1 Immunological mechanisms of specific immunotherapy.

there are group effects, there is no direct relationship to clinical efficacy in individuals.

SIT for Venom Anaphylaxis

Anaphylaxis to Hymenoptera venom is relatively rare but can be fatal. Venom-specific IgE antibodies can be found in 30–40% of adults for a few months following a sting, but usually these disappear subsequently. Some individuals develop high concentrations of venom-specific antibodies, which may persist for many years without further stings. This group of patients is at risk of anaphylaxis to subsequent stings: a small number die of anaphylaxis each year. Fatality rates are hard to estimate, perhaps 10–20 deaths/year in the United States.

Before embarking on venom immunotherapy (VIT), the patient needs to be carefully assessed, and some account should be taken of the natural history of the venom allergy.[5] Patients who have experienced systemic symptoms after stings are at much greater risk of anaphylaxis on subsequent stings, compared with patients who have only had large local reactions. The frequency of systemic sting reactions in children and adults with a history of large local reactions is about 5–10%, whereas the risk in patients with previous systemic reactions is about 30–70%. In general, there is a lower risk of repeated systemic reactions in children and in those with a history of milder reactions. In adults, the risk of systemic reaction to field stings diminishes over 10–20 years toward 15–30% (Fig. 91.2), but does not return to the background general population prevalence (3%). Children with a history of cutaneous systemic reactions had <5% risk of anaphylaxis during observation for 10–20 years. No test can accurately predict the outcome of the next sting. Live sting challenges have been used in research but are not practical or acceptable in clinical practice. Unfortunately, sting challenges are not absolutely predictive, since patients who do not react to laboratory challenge stings may react to subsequent field stings.

In deciding to recommend VIT, account should be taken of occupational and geographical factors that affect the likelihood of future stings. Bee stings are much more common in beekeepers, their families, and neighbors, whereas wasp stings tend to be sporadic but are an occupational hazard for bakers, gardeners, outdoor caterers, greengrocers, and other similar trades. Other factors to consider are the potential risks of emergency treatment with epinephrine and medical contraindications to VIT (see below). Large local reactions to stings are not regarded as indications for VIT, as they are not life-threatening and do not predict future problems, but there is some evidence they can be attenuated by VIT.[6]

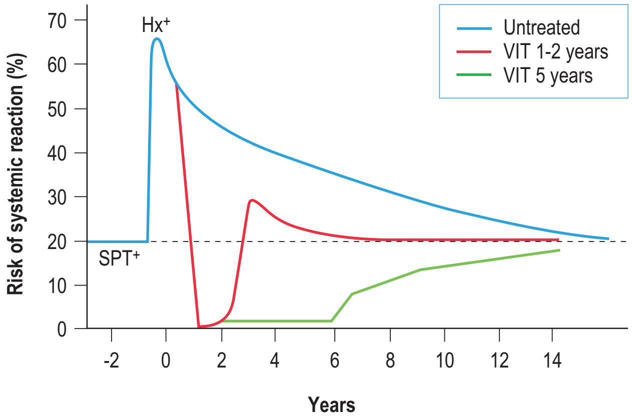

FIG 91. 2 Risk of systemic reaction (SR) from wasp stings over time after an anaphylactic event, and the effect of specific-allergen immunotherapy for 1–2 years or 5 years on the natural history. VIT, venom immunotherapy. (Adapted from Golden DB, et al. Survey of patients after discontinuing venom immunotherapy. J Allergy Clin Immunol 2000; 105: 385–90.)

VIT accelerates the process of risk reduction and confers rapid protection against field and laboratory stings. There is a low risk of systemic reaction (≈10%) for many years after discontinuing VIT. Although most reactions to stings after completing VIT are mild, fatalities have been reported in patients with other risk factors (mastocytosis, severe historical reactions, systemic reaction during VIT). This raises the question whether VIT should be life long, although lifelong treatment would alter the cost–benefit analysis. In children, the chance of systemic sting reactions remains <5% for up to 20 years after discontinuing VIT.

In summary, desensitization with venom preparations provides protection against field and laboratory stings, but some patients will still react despite completing VIT. The residual risk of systemic reactions to stings after VIT is about 10%, but these are usually mild. Patients undergoing VIT for venom anaphylaxis are usually offered injectable epinephrine and other antiallergic medication to use if stung during VIT, but this is unnecessary once they are on maintenance doses.

Assessing Effectiveness in Clinical Trials of SIT for Asthma and Rhinitis

The two main keys to success in designing any clinical trial are application of appropriate criteria for subject recruitment and selection of appropriate clinical endpoints (Table 91.1). In allergic rhinitis, efficacy is generally assessed in terms of symptom scores, recorded daily on diary cards or personal organizers.[7] Several symptom scales are in use, which all rely on a categorical grading system (*e.g.*, 1 = mild, 2 = moderate, 3 = severe, etc.). These measures carry the implicit assumption that the step from 1 to 2 is clinically equivalent to the step from 2 to 3. By assigning numerical values to nonparametric variables, one may either overestimate or underestimate the true effects of therapy. Reduction in rescue medication use is also measured, as, in theory, symptoms can improve because patients use more medication. In practice, most studies that showed improved symptom scores showed parallel reductions in medication use, but some studies showed reductions in medication use without a statistically

TABLE 91.1 Endpoints for Trials of Specific Immunotherapy in Asthma

Spirometry	Air flow obstruction (forced expiratory volume per second [FEV_1], peak expiratory flow rate [PEFR]) Bronchial irritability (histamine/methacholine PC_{20})
Symptoms	Wheeze, nocturnal waking, cough, breathlessness, time off work/school (diary cards or visual analogue scales)
Drug use	Bronchodilator use as surrogate for symptoms
Cost–benefit ratio	Reduction in other drugs, lost work, etc. compared with costs of specific-allergen immunotherapy (SIT) and time lost due to SIT
Safety	Frequency of local and systemic adverse events
Immunology	Allergen-specific immunoglobulin G4 (IgG4) Skin test responses Nasal allergen challenge responses Inhalation allergen challenge responses

significant reduction in symptoms. Combining symptom and medication scores is fraught with difficulty. It is almost impossible to agree on equivalences between different drugs, let alone the relative value of one antihistamine tablet versus a day when symptoms are moderate rather than mild.

When assessing improvement in asthma, it is important to remember that the majority of patients with atopic asthma have relatively mild disease that is usually easy to control with standard doses of conventional antiasthma drugs. Cases of severe asthma are relatively few in number, and the role of allergy in driving their disease is often less obvious than in mild cases. In mild cases, resting spirometry will usually be close to predicted values, so there is little scope for improvement in simple spirometric measures, such as forced expiratory volume per second (FEV_1). Peak expiratory flow rates (PEFRs) may show improvement after SIT, especially the early morning values, which are more likely to be reduced below the patient's best possible value compared with evening peak flow rates. Objective measures of bronchial irritability are more useful markers of improvement and a shift in the concentration of histamine or methacholine needed to induce a 20% fall in FEV_1 (PC_{20}) is commonly used. This measurement can be quite variable within individuals, so the minimum change that would be clinically significant is a change of at least one doubling dilution in the group geometrical mean PC_{20}. Other bronchial challenge tests, such as exercise challenge or adenosine inhalation, may provide additional insights into the ability of an antiasthma treatment to prevent acute attacks. Both these parameters depend indirectly on the PC_{20}, so again, it is important to consider statistical and biological significance separately.

Although these challenge models are useful surrogates for evaluating antiasthma treatment, more weight should be placed on improvements in the symptoms or progression of the disease than on protection against laboratory challenges. Lately, there has been a move to assess efficacy in terms of improvements in quality of life or health gain per unit cost. These analyses are becoming increasingly sophisticated but require careful validation to ensure that the quality-of-life instrument is sensitive to the illness being studied and that the economic model is realistic.

Finally, many trials of SIT for asthma and rhinitis have studied laboratory surrogate markers, such as changes in IgG subclasses, T-cell function, or skin test responses. Although such paraclinical measures do change during SIT and can shed light on the mechanisms of successful SIT, they cannot be used to provide direct evidence of clinical efficacy. Studies that show antibody or T-cell changes without direct clinical evidence of efficacy neither support nor undermine the established evidence that SIT works, albeit in mysterious ways, to improve the symptoms of appropriately selected patients. Recent research on paraclinical measures has identified four areas that may prove useful in future: dendritic cell (DC) markers in sublingual immunotherapy (SLIT)[8]; innate lymphoid cells (ILCs) favoring Th2 development (ILC-2), which have been show to decrease in frequency after successful SIT; decreased expression of diamine oxidase—the enzyme responsible for making histamine; and IgG antibodies that block IgE-mediated functional antigen presentation.[9]

SIT for Allergic Rhinitis

Allergic rhinitis is the main indication for SIT worldwide. As with all uses of SIT, it is important to select patients appropriately. The allergic basis of the rhinitis should be carefully assessed during history taking and skin or blood tests for IgE, and other relevant causes should be excluded. Tests of nasal sensitivity are not used in routine clinical practice but may be useful for assessing effectiveness in clinical trials.

The effectiveness of SIT in seasonal allergic rhinitis has been confirmed in many trials, using grass, ragweed, and birch pollen. Moreover, SIT has been shown to be clinically effective even in patients with severe seasonal rhinitis that is resistant to conventional drug therapy.[10] Data regarding the long-term efficacy of SIT for allergic rhinitis are limited, but formal studies have shown that the effects last for at least 3 years after discontinuing therapy.[11] Longer-term studies are difficult to conduct, but efficacy has been shown for up to 10 years in open studies. The benefits of SIT for perennial rhinitis are less well established than for seasonal rhinitis. In part, this reflects the difficulty in determining the extent to which allergy is responsible for perennial symptoms. Allergy to house dust mite (HDM) is common, but only about 50% of those with positive skin tests have symptoms. Conversely, there are other causes of perennial rhinitis, including vasomotor instability, infection, aspirin sensitivity, and so on. Nevertheless, clinical trials have shown a definite benefit provided the subjects are appropriately selected.[12] Clearer evidence of efficacy has been obtained in rhinitis caused by pet allergy. Several studies have shown a marked improvement in tolerance of cat exposure after SIT, confirmed both on challenge tests and simulated natural exposure.[13]

As with any therapy, the risks and cost-effectiveness of SIT need to be assessed on a case-by-case basis. Current drug therapy for rhinitis can be very effective, but about 60% of patients with seasonal allergic rhinitis report inadequate symptom control, even when taking maximal doses of antihistamines and intranasal glucocorticoids. Others experience nose bleeds caused by intranasal steroids and drowsiness caused by antihistamines. Moreover, we are now more aware of the adverse effects of rhinitis on quality of life. SIT offers a useful option for these patients as well as a logical approach to dealing with the underlying problem.

SIT for Asthma

Immunotherapy has been widely used to treat allergic asthma, but evidence of severe adverse reactions, including a small number of fatalities, has led to SIT being abandoned for asthma treatment in the United Kingdom since 1986, although asthma remains a common indication for SIT in North America and continental Europe.[12,14] There is no doubt that SIT is effective on asthma symptoms and protects against specific and nonspecific triggers. However, the role of allergic sensitization in ongoing asthma is less clear than for rhinitis, and the risks of therapy are undoubtedly greater in asthma. Current drug therapies for asthma aim to suppress the airways inflammation and smooth muscle contraction, which are characteristic features of asthma. None of these treatments is curative, and asthma recurs rapidly upon cessation of treatment. Moreover, current drug therapies are directed against downstream mechanisms rather than against the agents that might cause asthma. Allergen avoidance has been proposed as a potentially useful maneuver in those with allergic asthma; however, although asthma control can be improved by extreme forms of allergen avoidance (*e.g.*, admission to hospital, sending children to holiday homes at altitude), there is little evidence that similar benefits can be achieved by using the type of allergen avoidance that can be achieved in suburban homes. Thus there is scope for improving asthma care and for identifying allergen-specific therapies. SIT offers the possibility of diverting the immune response away from the allergic pattern and toward a more protective or less damaging response.

The efficacy of SIT in adult asthma has been assessed in many trials over the last 60 years. The results of these studies are difficult to interpret, either because poor quality allergen extracts were used or because of poor study design. Many trials were not placebo controlled; they were either open or single-blind studies; and in most cases, only small numbers of patients were treated. A 2010 meta-analysis[14] reviewed all of the relevant papers published between 1954 and 2008. Many of the earlier trials had methodological flaws, but there are sufficient data for general conclusions to be drawn. Symptom scores improved in the treated groups—it was necessary to treat four patients to prevent one from experiencing exacerbation of symptoms, and to treat five to prevent one from needing an increase in medication. SIT reduced the airways response to inhalation of specific allergen and also improved nonspecific bronchial reactivity.

In double-blind placebo-controlled (DBPC) trials in patients with grass pollen asthma, active treatment led to a 60–75% reduction in symptom scores compared with placebo-treated patients. Similar results were found in ragweed allergy with improved peak flow rates during the pollen season and reduced hay fever symptoms and sensitivity to laboratory challenge with ragweed pollen extracts. However, the associated economic analysis indicated that the cost saving in asthma drugs was less than that in SIT. The value of SIT is thus dependent on its ability to improve symptoms and quality of life rather than to reduce the costs of other medications.

In patients with asthma who are sensitive to cats, SIT with standardized aqueous extracts reduces the early asthmatic response to inhaled allergen and attenuates responses to room exposure to cats. Interestingly, these studies showed a clear delay in onset of symptoms and an overall reduction in symptoms and peak flow recordings after simulated exposure to cats, but there was no protection against allergen-induced increases in nonspecific bronchial hyperresponsiveness. Another study of cat SIT for asthma using a depot preparation found a reduction in both specific and nonspecific bronchial reactivity (to cat extract and histamine, respectively). There is, however, no hard evidence that SIT is of benefit to treat asthma caused by dog allergy.

Several DBPC studies have examined the effects of SIT in patients with asthma who are sensitive to HDM. Early studies used tyrosine-adsorbed or depot preparations, which yielded conflicting results, with reductions in drug requirements in children but no improvement in asthma control in adults. Subsequent studies using more modern extracts have found beneficial effects on symptoms, antiasthma medication use, and bronchial hyperresponsiveness.

SIT for Food Allergy

After several false starts, research has now shown that it is possible to tolerize patients to food allergens, such as peanut. Arguments continue over what to call this, as the tolerance achieved seems to be temporary, and patients become fully sensitive again if they stop treatment. However, the possibility to render patients with life-threatening food allergy tolerant of the relevant food is a useful step forward. In line with the clinical time course, it has been shown that basophil sensitivity is suppressed early during peanut tolerization but returns to baseline when treatment is stopped. In contrast, in patients undergoing SLIT for aeroallergen sensitivity their basophil reactivity takes longer to drop away after starting treatment, but once achieved, the effect on basophils is sustained for months or years after ceasing SLIT. This differential effect on surrogate markers suggests that: (i) current forms of oral immunotherapy (OIT) for food allergy are achieving a temporary remission; (ii) strategies that are more efficacious against basophil reactivity may offer a more sustained state of tolerance.[15] In parallel, work is ongoing to develop injection SIT for fish allergies.[16]

Comparison of SIT With Other Therapies

The majority of clinical trials of SIT for asthma have compared SIT either with untreated historical controls or with a matched placebo-treated group. To date, the effectiveness of SIT in asthma has rarely been compared with conventional management (avoidance measures and inhaled or oral antiasthma drugs).

Effects of SIT on the Natural History of Allergic Disease

In recent years, there has been increasing interest in the possibility that SIT may have disease-modifying or preventive effects. These are important not only in their own right as desirable outcomes but also as factors in the economic evaluation of SIT.

Children often start with a limited range of allergic sensitivities and progress over time to develop IgE against a wider range of inhaled allergens. Treatment with SIT may limit this tendency to acquire new sensitizations, although the clinical benefit of this preventive effect is not clear. In the most widely cited study, children with asthma who were sensitized only to HDM were treated with HDM-SIT. Of the 19 treated children, 10 did not develop new sensitizations, whereas all 22 untreated children acquired new sensitivities, in many cases to more than one new allergen.[17] A long-term study of treatment with a grass pollen allergoid has confirmed this observation, with 50% fewer new sensitizations 12 years after completion of the course of SIT.[18] Similar results have been found in a study of children treated with SLIT, in which 3% of SLIT-treated children and 34% of control subjects developed new sensitizations within 3 years.[19] It seems probable that this effect is indirect. In other words, it is unlikely that HDM-SIT directly affects the B cells that recognize cat or grass pollen, but by treating the HDM allergy, SIT may reduce inflammation in the nose and hence modify the likelihood that exposure to other allergens will lead on to sensitization.

Each year, a proportion of patients with allergic rhinitis go on to develop asthma. This rate of progression has been estimated at 5% per annum in college students,[20] but this remains, perhaps surprisingly, an area of considerable uncertainty. Several long-term epidemiological studies are now in progress, under the auspices of the International Study of Asthma and Allergies in Childhood (ISAAC), and these should eventually shed light on the rate of progression at different ages and the extent of regional and international variation. It has been suggested that SIT may modify the natural history of asthma in children who have allergic rhinitis but have not yet developed asthma. Data to support this proposition are limited. In the key study, a group of 205 children aged 6–14 years, without previously diagnosed asthma, were treated with SIT for birch or grass pollen allergy in an open randomized design. Three years after completing treatment, 45% of the untreated group had developed asthma, whereas only 26% of the treated group had asthma. These results have been sustained out to 7 years after completing therapy. Thus in terms of number needed to treat, four children had to be treated to prevent one case of asthma, which makes this an extremely effective therapy.[21] Similar results have been reported with SLIT: After 3 years of SLIT, 8 of 45 SLIT-treated children and 18 of 44 control subjects had developed asthma, representing a relative risk of 3.8 for untreated subjects compared with the actively treated group.[22]

SIT may also modify the progression of established asthma. An early open study using uncharacterized mixed allergen extracts supported this view, with about 70% of treated children losing their asthma after 4 years therapy, compared with about 19% of untreated controls, a result that was sustained up to the age of 16 years. The proportion of children whose asthma was severe at age 16 years was also much lower in the treated group.[23] In this period, when clinical trials were conducted differently, well before the days of ethics committees, Johnstone and Dutton randomized all children attending their clinic between August 1953 and January 1955 to one of four treatments. Neither the subjects nor their parents were aware of the treatment being given. Compared with those who received placebo or very dilute allergens, those treated with the two higher doses of SIT were much more likely to lose their asthma after 4 years, and among those whose asthma persisted, the likelihood of having severe disease was much lower in those who had received active treatment. Although it would be very difficult to conduct such a study today, the data are useful in confirming the dose–response relationship in SIT and its potential for reducing the duration and severity of asthma. A prospective, nonrandomized, open-label study of SLIT has reported that children with asthma who received SLIT had less asthma compared with those on standard medication after 4–5 years, and this difference persisted for 5 years after cessation of treatment.[24]

In contrast, there is no current evidence that SIT influences the evolution of established asthma in adults. In part, this reflects the reluctance of physicians to use SIT to treat patients with severe asthma. Studies that have investigated withdrawal of therapy have reported rapid recurrence of asthma symptoms, although rhinitis symptoms seem to show much more sustained relief after SIT.[25]

In summary, there is persuasive evidence that both subcutaneous and sublingual immunotherapy can modify the course of allergic disease, by reducing the incidence of new sensitizations, and by preventing or slowing the development of clinical asthma. The mechanisms that underlie these observations are not fully understood. It is likely that a combination of immunological and structural alterations is involved. Economic evaluations of the benefits of SIT and SLIT need to take on board these preventive effects to arrive at a full cost–benefit analysis.

SAFETY

The main factor preventing the wider adoption of SIT is the risk of serious adverse reactions. In general, SIT is quite safe in patients who do not have asthma, but a significant number of deaths have been reported in the United Kingdom and the United States when SIT was used to treat patients whose asthma was unstable.[26] The incidence of systemic reactions in patients receiving SIT for asthma varies among study series and has been reported to range from 5% to 35%. In contrast, serious systemic reactions occur after about 1 in 500 injections in patients with rhinitis. Some adverse events are caused by administration of the wrong dose, which underscores the importance of checking doses carefully before each injection. Others occur during changeover from one vial to another. Most allergists, therefore, cut back on the dose when changing vials to minimize this risk. Systemic reactions are much more likely if the patient has an intercurrent viral illness, so doses should be delayed if the patient is unwell or has any signs of active asthma.

On a separate note, there is general agreement that SIT should not be used in patients with autoimmune disorders or malignant disease. Although there is no hard evidence that SIT is actually harmful in these groups, it seems unwise to attempt manipulation of the immune system in such patients, not least because of the risk that spontaneous and unrelated variations in the autoimmune disorder or cancer may be blamed on SIT. Other medical contraindications to SIT include significant coexistent cardiac disease, which may be exacerbated by any adverse reactions to SIT. Patients on beta-blockers should also not receive SIT. Although they are not at increased risk of adverse reactions, their physiological response to the cardiovascular component of anaphylaxis will be impaired, and they will not respond to the epinephrine that is used to treat adverse reactions to SIT.

SUBLINGUAL IMMUNOTHERAPY

High-dose topical immunotherapy regimes were used in the first half of the twentieth century but then lost ground to injection immunotherapy in conventional medical practice. Over the past 20 years, there has been a resurgence of interest in SLIT, which is based on the concept that allergens given via the mucosal surface can induce immunological tolerance, without carrying the same risk of systemic reactions that is found with injection SIT. Moreover, SLIT is more appealing to patients, especially to those who cannot easily find time to attend clinic for injection SIT.[27] In animal models, IgE responses to allergens can be reduced or prevented by oral administration of allergen. Most of these models involve feeding in early life to prevent subsequent acquisition of sensitivity, so this is a different scenario from the usual clinical context of treating established allergic disease. The precise mechanisms by which "oral tolerance" is induced remain unclear, but it seems likely that the route of allergen processing and presentation is a critical determinant of the subsequent T-cell response (Chapter 6). In mice, locally administered allergen is taken up by mucosal DCs and then presented to T cells together with IL-12, biasing the response toward a Th1-like profile and away from the pro-IgE Th2 profile. In contrast to the animal models, the immunological response to SLIT in human studies has been relatively modest. Some changes have been found in skin sensitivity, but most studies have not found any change in systemic parameters, such as specific IgE, specific IgG, or T-cell cytokine balance.[28]

Nevertheless, a body of evidence has accumulated from well-conducted clinical trials, indicating that SLIT can be effective, with up to 30–40% reductions in symptom scores and rescue medication use in seasonal allergic rhinitis.[29] SLIT treatment regimes typically involve a rapid buildup phase followed by treatment about three times per week with rapidly dissolving tablets containing allergen extracts. Some preparations are supplied in liquid form, with a calibrated dropper. Several large clinical trials of SLIT have shown clinically and statistically significant reductions in symptom and medication scores, supporting the conclusions of previous meta-analyses of SLIT, which assessed the earlier, less well-designed studies that were individually small and inconclusive. The meta-analysis estimated the efficacy of SLIT as being about two-thirds of that seen in comparable studies of injection SIT, but the most recent studies have shown levels of efficacy that are equal to the best recent multicenter trials of injection SIT. However, the efficacy may be greater for pollens than for HDM allergies.[30] Local side effects are common with SLIT but are generally well tolerated. Systemic side effects of SLIT are very rare but have been reported, especially in patients who have previously had systemic reactions to injection SIT. SLIT is now being used routinely in some parts of Europe (especially Italy and France), but the doses and regimes being prescribed are often different from those that were used in the clinical trials. Overall SLIT should widen the scope of SIT and allow more patients to be treated. As with all forms of immunotherapy, patient selection remains the key to ensuring that therapy is targeted to those who are likely to benefit from it.

FUTURE DIRECTIONS

There is clearly scope to improve conventional SIT. Possible avenues include the use of recombinant allergens, which should make it easier to standardize allergen vaccines and may allow fine-tuning of vaccines for patients with unusual patterns of reactivity. Most patients with allergies react to the same components of an allergen extract, the so-called major allergens, which are defined as those allergens recognized by over 50% of sera from a pool of patients with clinically significant allergy to the material in question. However, not all patients recognize all major allergens, and some patients only recognize allergens that are not recognized by the majority of sera of patients with allergies. This latter group may not respond to standard extracts but might be better treated by a combination of allergens to which they are sensitive. Until the advent of molecular cloning, this has been impossible to achieve. Now that recombinant allergens for SIT are available, the range of sensitivities can be better characterized, and this may lead to patient-tailored vaccine products. Thus far, clinical trials have confirmed that recombinant allergen cocktails are effective, but these have not yet shown superiority over conventional vaccines.[31] Regulations are the major barrier to this development: Under current regulations, each combination of allergen components would have to be developed as a freestanding pharmaceutical. Until a different regulatory framework is agreed upon, recombinant allergens will only be tested as fixed combination cocktails.

Another alternative approach is to inject allergens directly into lymph nodes, under ultrasound guidance. Proponents of this approach argue that after subcutaneous injection, less than 1% of the injected material reaches the lymphatic system; therefore if the benefit of SIT is driven by the dose, then direct intranodal administration should be more efficient and also safer than conventional SIT. Early studies with doses of about 1% of standard SIT showed immunological efficacy, with some signs of clinical efficacy and reduced risks of side effects.[32] However, subsequent clinical trials by other groups have not demonstrated efficacy.[33,34]

Novel forms of allergenic molecules may be created: for example, a recombinant trimer consisting of three covalently linked copies of the major birch pollen allergen, Bet v 1 has been made. This trimer is much less allergenic, even though it contains the same B-cell and T-cell epitopes as the native molecules and induces Th1 cytokine release and IgG antibodies, analogous to the antibody response to standard SIT.[35] Folding variants and other modifications of the physical structure may also improve the safety of SIT.

Since the epitopes recognized by IgE molecules are usually three-dimensional, while epitopes recognized by T cells are short linear peptide fragments of the antigen (Chapter 6), it should be possible to manipulate allergens and reduce their ability to bind to IgE or to create peptide fragments, which will modulate T cells without the risk of anaphylaxis. Cross-linking allergen proteins with aldehydes reduces their ability to bind antibodies. Such allergoids do not degranulate the basophils of sensitized individuals *in vitro* but are recognized by allergen-specific T cells. Clinically, allergoids have shown efficacy in rhinitis caused by grass pollen or HDM.[36]

Short peptide sequences that should not be recognized by IgE antibodies can be used as vaccines as well.[35] Peptide vaccines can be either natural sequences or altered peptide ligands. If high doses of natural peptides are given, these deceive the T cell into high dose tolerance. Altered peptide ligands induce anergy by providing an incomplete activation signal. Both approaches are affected by the MHC type of the individual undergoing treatment. By sequential alteration of HDM allergen Der p peptides, it is possible to suppress proliferation of T-cell clones recognizing native Der p peptides, as well as suppressing their expression of CD40 ligand and their production of IL-4, IL-5, and IFN-γ. These anergic T cells do not provide help to B cells to switch class to make IgE; importantly, this anergy cannot be reversed by providing exogenous IL-4. In humans, the main focus has been on cat allergen (Fel d1) peptides, which can reduce the level of symptoms on exposure to cat dander.[37] Similar studies with the peptides of phospholipase A2 (PLA2, a major allergen in bee venom) have also been reported. However, to date, peptide vaccines have not shown any greater efficacy compared with conventional vaccines.

In an animal model, intranasal application of genetically produced hypoallergenic fragments of Bet v1 produced mucosal tolerance with significant reduction of IgE and IgG1 antibody responses, as well as reduced cytokine production *in vitro* (IL-5, IFN-γ, IL-10). These reduced immunological responses were accompanied by inhibition of the cutaneous and airway responses that were seen with the complete Bet v 1 allergen. The mechanisms of immunosuppression seemed to be different for the allergen fragments and the whole molecule, in that tolerance induced with the whole Bet v 1 molecule was transferable with spleen cells, whereas that induced by the fragments was not.[38]

From epidemiological and experimental studies, we know that vaccines with mycobacteria have antiallergic properties. In Japan, early vaccination with the Bacille Calmette-Guérin (BCG) vaccine was associated with a substantial reduction in the risk of developing allergy,[39] although similar associations were not evident in studies in Sweden.[40] In an animal model, administration of the BCG vaccine before or during sensitization to ovalbumin reduced the degree of airway eosinophilia that followed subsequent challenge with ovalbumin. This effect was not mediated through any direct effect on IgE production or blood eosinophil numbers but was mediated through IFN-γ and could be reversed by exogenous IL-5.[41]

Two new approaches using DNA vaccines are also undergoing serious consideration. The first of these is a general approach, using CpG oligodeoxynucleotides (ODN), which mimic bacterial DNA, binding to T-cell receptor-9 (TCR-9) and stimulating a Th1-type cytokine response. This technology is essentially a refinement of vaccination adjuvant technology, since CpG ODN have been shown to be the principal activity from complete Freund adjuvant. In a mouse model of asthma, preadministration of CpG ODN prevented both airway eosinophilia and bronchial hyperresponsiveness. Moreover, these effects were sustained for at least 6 weeks after CpG ODN administration.[42] Alternatively, CpG ODN can be coupled to the allergenic protein, which enhances immunogenicity in terms of eliciting a Th1-type response to the allergen but reduces its allergenicity and stimulates Th1 cytokine expression in cultured human peripheral blood mononuclear cells (PBMCs).[43] Initial clinical trials confirmed that the hybrid vaccine elicits a Th1-pattern response,[44] but the results of subsequent trials have been inconclusive. A contrasting approach is immunization with allergen-specific naked DNA sequences. This technology is still in its infancy, but preliminary data suggest that administration of naked DNA leads to production of allergens from within the airway epithelial cells.[45] It seems that the endogenously produced allergen elicits a Th1-type response, due to the different handling pathways for endogenous and exogenous allergens. If this can be reproduced in humans with allergies, this may overcome the existing Th2-pattern response and eliminate the allergy. However, the potential for generating a powerful Th1-type response to ubiquitous agents means that this approach needs careful evaluation in animal models before it can be pursued in humans.

The recent introduction of monoclonal antibodies (mAbs) directed against IgE offers another option. Treatment with anti-IgE reduces immediate and late-phase responses to inhaled allergens and should also reduce the risk of adverse effects from SIT injections. Moreover, when anti-IgE is combined with conventional SIT, the effects on seasonal allergic rhinitis are additive.[46] However, the high cost of anti-IgE and the need for regular injections are likely to limit its use to patients who have severe allergic disease that cannot be managed by other means, and these patients are not generally suitable candidates for SIT.

CONCLUSIONS

ON THE HORIZON

New Technologies for Immunotherapy

- Recombinant allergens
- T-cell peptide vaccines
- T-helper cell-1 (Th1) immunostimulants (*e.g.*, mycobacteria, CpG)
- Allergen-immunostimulant complexes
- Anti–immunoglobulin E (IgE)
- New routes of administration:
  - Sublingual
  - Intralymphatic
  - Epicutaneous
  - Liposome encapsulation

SIT has been established as a treatment for allergic rhinitis and for venom hypersensitivity but is more controversial for treating allergic asthma. When used in appropriately selected patients, SIT is effective and acceptably safe, but care must be exercised in recognizing and treating adverse reactions. Appropriate training of allergists and SIT clinic support staff is essential. Despite a century of use, the precise mechanisms of action of SIT remain uncertain. Current emphasis on the role of Tregs is leading to renewed attempts to simplify SIT regimes and reduce its risks. Future directions in SIT include the development of vaccines that are better standardized and the use of recombinant allergens, both of which should improve the safety profile of SIT. In parallel, and perhaps for the longer term, we should explore the development of general immunomodulatory therapies, which would be particularly advantageous for those patients sensitized to multiple allergens.

MULTIPLE-CHOICE QUESTIONS

1. Successful immunotherapy may work through induction of:
   A. B-cell tolerance
   B. Allergen-specific immunoglobulin A (IgA) antibodies
   C. FOXP3$^+$ regulatory T cells
   D. Tryptase$^+$ mast cells

2. Venom immunotherapy:
   A. Prevents large local reactions
   B. Accelerates the rate of tolerance
   C. Confers long-lasting efficacy after 1 year of treatment
   D. Permanently prevents systemic reactions

3. Changes in allergen-specific immunoglobulin G4 (IgG4):
   A. Reflect the dose of allergen injected
   B. Predict response at the individual level
   C. Are caused by induction of interleukin-17 (IL-17)
   D. Can be used to predict clinical efficacy

4. Immunotherapy is a proven treatment for allergy to:
   A. Dog dander
   B. Walnuts
   C. Hen's egg
   D. Tree pollen

Flow Cytometry

Sergio D. Rosenzweig

Flow cytometry has become a standard laboratory tool in the evaluation of hematopoietic cells, including the identification of leukocyte populations and subpopulations, a method referred to as *immunophenotyping.* The clinical application of this technology has been facilitated by the development of instruments and data analysis systems suitable for routine use in diagnostic laboratories. In addition, the expanded range of monoclonal antibodies (mAbs) specific for lymphocyte (and other hematopoietic cell) surface antigens directly conjugated to a number of different fluorescent indicators (fluorochromes) provide an extensive panel of reagents that facilitate multicolor (polychromatic) studies.

The clinical needs that pushed this technology date back to the emergence of absolute CD4 T-cell counts as a critical measure for disease assessment and follow-up in managing patients infected with human immunodeficiency virus (HIV). Flow cytometry applied in the monitoring of HIV infection was followed by the routine application of cell characterization by flow cytometry in the evaluation of hematologic malignancies and, more recently, in the study of immunodeficiency disorders and other immune-mediated diseases.

Recent advances in instrumentation and fluorochrome chemistry now allow for routine polychromatic flow cytometry studies, with concomitant assessment of cell surface markers and intracellular parameters, including intracellular proteins, phosphoproteins, and cytokines, as well as identification of changes linked to cellular activation and apoptosis. Intracellular flow cytometry also can be applied to evaluate cell cycle status (*i.e.,* G_0-G_1, S, G_2-M) based on DNA staining, which is useful in evaluating tumor cells and assessing the *in vitro* lymphocyte response to various stimuli. Additionally, evaluation of lymphocyte proliferation can be performed with cell tracking dyes that allow quantitation of the rounds of cell division associated with cell activation, and techniques to assess immune cell mediated cytotoxicity have also been developed. Finally, characterization of antigen-specific T cells following immunization or associated with normal and/or abnormal immune responses in association with disease states can be accomplished by using multimer technology as well as intracellular cytokine detection following antigen exposure.

This chapter focuses on the basic concepts of flow cytometry, including instrument characteristics, data management, lymphocyte gating, and directed use of test reagents. In addition, it provides a brief overview of intracellular protein detection, cell activation and cell-mediated cytotoxicity studies, cell cycle analysis, apoptosis detection, and multimer technology, focusing on the appropriate application of these approaches as well as their limitations.

INSTRUMENTATION

The basic components of a flow cytometer, as shown in Fig. 92.1, include an illumination source, an optical bench, a fluidic system, electronics, and a computer.[1] Briefly, stained cells flow into single file by the fluidic system and are interrogated by one or more light sources; these sources generate light signals, which are directed by the optical system to the photodetectors, which, in turn, convert light into electronic signals for storage and subsequent analysis. This process is discussed further in the section below.

The fluidic system lies at the heart of the flow cytometer and consists of isotonic sheath fluid that moves the sample stream containing the cells. This is accomplished by injecting the cell sample into flowing sheath fluid, establishing a hydrodynamically focused single-file flow of cells (particles) that move through the analysis point while maintaining the cell stream in a constant, central location.[2] The centrally focused cell stream ensures that the illumination of all cells is virtually equivalent. Thus the difference in magnitude of the emission signal(s) generated from each cell reflects biological differences between the cells (rather than reflecting the variation in the illumination energy if the cells were not tightly focused). The use of hydrodynamic focusing has the additional advantage of producing little or no change in cell shape, although it may have an effect on cell orientation. The consistency in maintaining cell shape facilitates distinguishing "architectural" differences between specific leukocyte types (see Gating section).[3] However, this method can generate single-file cell rows with precision only up to a flow rate of 60 to 100 μL/min, which can lead to long acquisition times for the detection of very rare events. To overcome this problem, recently introduced flow cytometry instruments utilize acoustic focusing, which align cells through the use of sound waves, allowing sample flow rates of up to 1000 μL/min, without loss of signal quality.[4,5]

Illumination in standard clinical instruments is generated by two or more lasers, each of which provides a specific monochromatic light source (*e.g.,* a sapphire laser generates a 488-nm-wavelength [blue] beam). Modern lasers are small and available in multiple wavelengths, including ultraviolet (350 nm), violet (405 nm), blue (488 nm), green (532 nm), yellow (560 nm), orange (610 nm), and red (633 nm), permitting the simultaneous use of multiple fluorochromes having different excitation

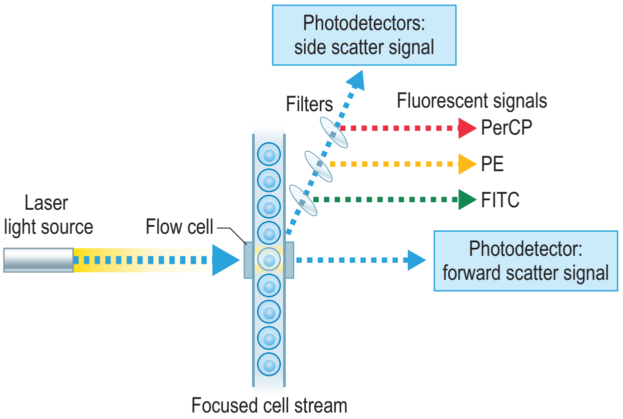

FIG 92.1 Simplified Design of A Flow Cytometer with One Illumination Source (Laser) Set Up to Collect Five Parameters. These include the two nonfluorescent parameters (blue light) forward and side scatter, as well as three fluorescent parameters, green (FITC), orange (PE), and red (PerCP) light.

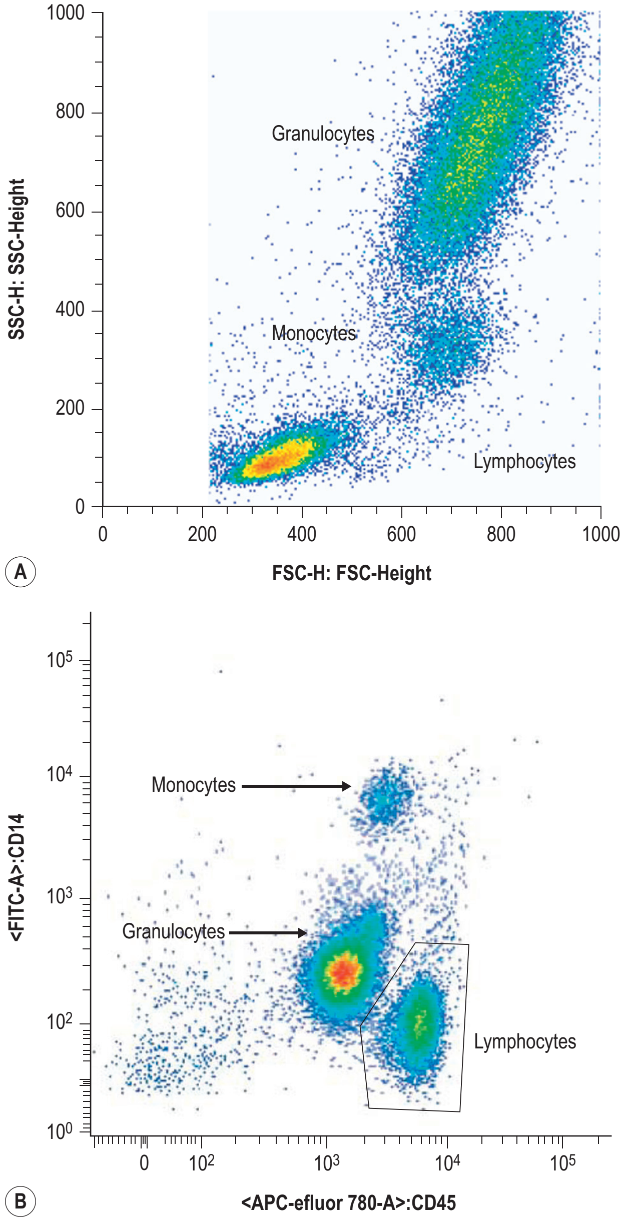

FIG 92.2 (A) Forward- and side-scatter dot plots on a lysed whole blood sample, demonstrating the basic three-part leukocyte differential with lymphocytes, monocytes, and granulocytes. (B) Dot plot with DC45/CD14 gating reagents showing the fluorescence distribution of all the three leukocyte types identified to include lymphocytes, monocytes, and granulocytes, as well as a small number of nonlysed red blood cells and/or debris.

requirements.[6] The point where the light illuminates the cell in analytical instruments occurs within a flow cell, while in cell sorters, the beam intersects cells flowing as a stream in air. The optical bench contains lenses that shape and focus the illumination beam to ensure consistent excitation energy at the analysis point.

The illumination of a cell generates both nonfluorescent and fluorescent signals, which are collected and measured by optically coupling the signal to a detection system consisting of filters, each of which is linked to a photodetector. The filters are chosen to allow the nonfluorescent signals to be measured at the same wavelength as the excitation signal (*e.g.,* 488 nm from a blue light source) for the forward- and side-scatter channels (see Gating section), whereas those for the fluorescence channels utilize specific filters that allow passage of light with wavelengths specific to each fluorochrome (*e.g.,* green, orange, or red; see Fluorochrome section). The number and arrangement of the photodetectors allows for the simultaneous evaluation of multiple colors (parameters) for each cell, with a report describing a modified clinical instrument capable of evaluating 17 or more colors simultaneously from each cell evaluated.[7]

The internal electronics in the flow cytometer provides the system for converting analog light signals (photoelectrons) received at the photodetectors into digital signals for acquisition and storage in a computer. The intensity of these converted signals is measured on a relative scale that is generally set in either 256 or 1024 equal increments (referred to as *channels*) for display and analysis. A number of specialized analysis programs are available, and results are depicted graphically as single-parameter histograms displaying specific light (fluorescence) intensity (*x*-axis) versus cell number (*y*-axis) (Fig. 92.2), or two-color displays where the *x*-axis and the *y*-axis reflect the light intensity of the two colors, and the cell numbers are represented via dot, pseudocolor, contour, or density plots (Fig. 92.3). Most analysis programs enable the operator to evaluate the number and percentage of events, mean and/or median channel fluorescence, and selected statistical measures for each identified cell, and these can be aggregated into specific populations and/or subpopulations of cells. Thus a flow cytometer provides a platform with the capacity to assess multiple pieces of discrete information (parameters) generated from each individual cell contained within a large number of cells present in the test sample, and these are typically accrued at rates of 1000–2000 (or more) cells per second.

FLUORESCENCE REAGENTS

Standard mAb reagents for clinical use are typically directly conjugated to a fluorochrome, a dye that absorbs and emits light of different wavelengths based on the energy lost during the return of excited electrons to their ground state associated with illumination by a specific wavelength of light. Thus the emitted light has a longer wavelength (lower energy) than the wavelength of the excitation beam. The number of commercially available fluorochromes has increased dramatically with the routine use of dye conjugates and instruments with three or more lasers.[8] Commonly used fluorochromes in clinical immunophenotyping include the organic dyes fluorescein isothiocyanate (FITC), phycoerythrin (PE), peridin chlorophyll protein (PerCP), and allophycocyanin (APC). Conjugations of PE and APC to cyanines (Cy5, Cy5.5, and Cy7) and Alexa Fluor dyes produce tandem dyes with additional emission spectra, based on energy transfer from one fluorochrome to the second fluorochrome serving as the source of emitted light. This allows for the simultaneous evaluation of 6–8 colors in most current clinical instruments with only two or three lasers.

One recent advance in the field was the development of a new class of inorganic fluorescent semiconductor nanocrystals, named *quantum dots* (QDs).[9] These particles are perfectly suited for polychromatic flow cytometry, as they have broad excitation spectra (525–800 nm) and sharp, discrete emission spectra that varies depending on their core size.[9] This means that QDs of different sizes (and consequently of different colors) can be excited by the same laser source, allowing simpler multiplexing.[9] In addition, QDs have high quantum yield, high molar extinction coefficients, and extraordinary resistance to photodegradation and chemical degradation. These qualities make them perfectly suitable for use in biological studies, including intracellular *in vivo* imaging, fluorescence resonance energy transfer (FRET) analysis, and dynamic imaging of single proteins for longer periods.[9]

Additional dyes are available for functional studies and include calcium-sensitive dyes (*e.g.,* fluo-3), glutathione-sensitive dyes (*e.g.,* monochlorobimane), and hydrogen peroxide (H_2O_2)–responsive dyes (*e.g.,* dihydrorhodamine 123 [DHR123]).[10,11] Assessment of DNA content can be performed with dyes that intercalate double-stranded DNA and RNA, including propidium iodide (PI) and ethidium bromide.[12] In addition, there are ultraviolet-excited dyes that are highly specific for DNA, including Hoechst 33258 and 4,6-diamidino-2-phenylindole (DAPI); acridine orange is used for simultaneous staining of DNA/RNA.[12]

DATA ANALYSIS

Gating

KEY CONCEPTS

Gating

- Method for defining cell population of interest
- Typically performed using forward scatter and side scatter and lineage-specific antibodies

The proper assessment of specific cell types within a mixture requires initial identification of lineage-specific cells, an approach referred to as *gating.* In practical terms, immunophenotyping focused on lymphocytes requires minimizing the nonlymphocytes included in the evaluation, and this is accomplished by lymphocyte gating. The standard sample for clinical studies is anticoagulated whole blood; directing the study to lymphocytes requires eliminating the great majority of nonlymphocytes from the collected data such that the expression of a percentage for a specific cell subpopulation is an accurate measurement. Without gating, data can also be negatively impacted by coexpression of surface antigens on different cell lineages (*e.g.,* CD4 is found on lymphocytes and monocytes at various densities). In addition, nonspecific binding of monoclonal reagents through Fcγ receptors, and the level of cytophilic human immunoglobulin (Ig), varies between cell types, making appropriate gating crucial to generate valid data. These techniques are also used to focus the evaluation on other hematopoietic cells, including monocytes, granulocytes, eosinophils, erythrocytes, and platelets.

Initial gating to focus on a specific leukocyte population typically involves the use of two nonfluorescent parameters, forward scatter (FSC) and side scatter (SSC) (see Fig. 92.2A).[3] FSC is a reflection of cellular cross-sectional area (direct relationship to cell size), whereas SSC is an indication of the cellular granularity. The combination of these two nonfluorescent parameters provides a three-part differential in red blood cell (RBC)–lysed whole blood that distinguishes between normal lymphocytes, monocytes, and granulocytes. As can be seen in Fig. 92.2A, among leukocytes, lymphocytes have the lowest FSC and SSC, monocytes have higher FSC and SSC, and granulocytes have the greatest SSC. This method is effective in distinguishing a relatively pure population of lymphocytes under most circumstances. However, the presence of nucleated RBCs, large platelets, basophils, or other particulate debris can produce contaminating events (cells) within this “lymphocyte gate.” Furthermore, malignant or activated lymphoid cells may not fit into the previously outlined standard light scatter patterns.

A method for confirming the integrity of the light scatter–based lymphocyte gate uses the directly conjugated monoclonal “gating” reagents anti-CD45 and anti-CD14.[13] These two mAbs more accurately identify the three-part differential. Lymphocytes have the highest level of CD45 binding but are negative for CD14; granulocytes have a lower level of CD45 binding and an intermediate level of CD14 expression; and monocytes have high levels of both CD45 and CD14 expression (see Fig. 92.2B). Importantly, nonleukocytes, including erythrocytes and platelets, are negative for these markers. However, malignant leukocytes that have characteristics of early precursor cells often have altered CD45 and/or CD14 expression, which must be recognized when studying hematological malignancies. Gating reagents provide a reliable means of checking the light scatter–based lymphocyte gate for the frequency of nonlymphocytes within the gate as well as the extent of lymphocyte exclusion from the gate. Guidelines for an acceptable degree of contamination within the lymphocyte gate, as well as the level of lymphocyte exclusion, are contained in the US Clinical and Laboratory Standards Institute guideline for lymphocyte immunophenotyping.[14] With the expanded use of polychromatic flow cytometry, some centers now include anti-CD45 in every tube to refine the gate and prevent cell contamination as described above.

Data Display

KEY CONCEPTS

Data Presentation

- Fluorescence intensity is plotted versus cell number.
- Flow cytometry can present cumulative data on more than one parameter for each cell.
- Multicolor data presentation can increase cell subpopulation resolution.

The simplest method for demonstrating flow cytometry data is the single-parameter histogram (see Fig. 92.2), a graphic presentation of cell number on the *y*-axis versus fluorescence (light) intensity from a single fluorochrome on the *x*-axis. Integration of curve areas provides the number of cells, and often there are two distinct distributions, one referred to as *negative* identifies cells that are not bound specifically by the monoclonal reagent, and the second represents cells bound by the antibody. Negative distribution actually reflects low-level fluorescence resulting from cellular autofluorescence together with any nonspecific binding of the monoclonal reagent(s), and the magnitude of both phenomena varies among different cell types. Interpretation of data is simplified when there are two distinct cell populations (*i.e.*, negative and positive), but the evaluation of two overlapping distributions is more difficult.

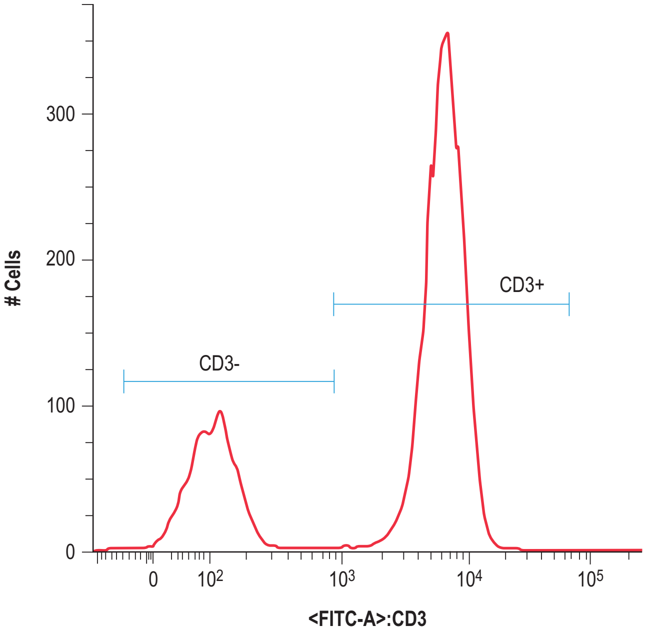

FIG 92.3 Single-parameter histogram for CD3 expression on lymphocytes demonstrating the negative, non–T-cell population (B cells, natural killer [NK] cells), and a positive T-cell population. Integrating the area under each curve would provide the numbers and percentage of cells present in each respective subpopulation.

Multiparameter data can be evaluated by using a series of single-parameter histograms that consider each fluorochrome independently. However, it is more informative to present two parameters simultaneously by using a correlated display (Fig. 92.4), and two-color displays are recommended for clinical flow cytometry.[15] This approach enables the simultaneous visualization of four different populations: A$^+$/B$^-$, A$^-$/B$^+$, A$^+$/B$^+$, and A$^-$/B$^-$. More recently, these displays were developed further to include a mixture of logarithmic (for higher intensity expression) and linear (for lower intensity expression) intensity for each axis to allow for better interpretation of events with very low, zero, or negative fluorescence. This combined-display approach resolves the previous problem of a large number of events being displayed compacted against the axes, even with properly compensated samples, and will be used in the illustrations throughout this chapter.[16]

The simultaneous use of *n* monoclonal reagents can identify a total of 2^n subpopulations. These different subsets can be identified sequentially by first dividing the cells into those that are positive versus those that are negative with one reagent and then evaluating the defined subpopulations for the remaining two reagents using a two-color approach. Alternatively, more modern software can represent multiple populations as polychromatic plots, which can simplify data analysis.[17] The polychromatic approach can provide a means to further resolve subpopulations and has been particularly useful in the evaluation of cellular differentiation, activation, and functional correlates, as well as clarifying overlapping cell subpopulations.

Positive–Negative Discrimination

The evaluation of clinical immunophenotyping data requires establishing criteria for the boundaries between negative or nonstained (autofluorescence plus nonspecifically stained)

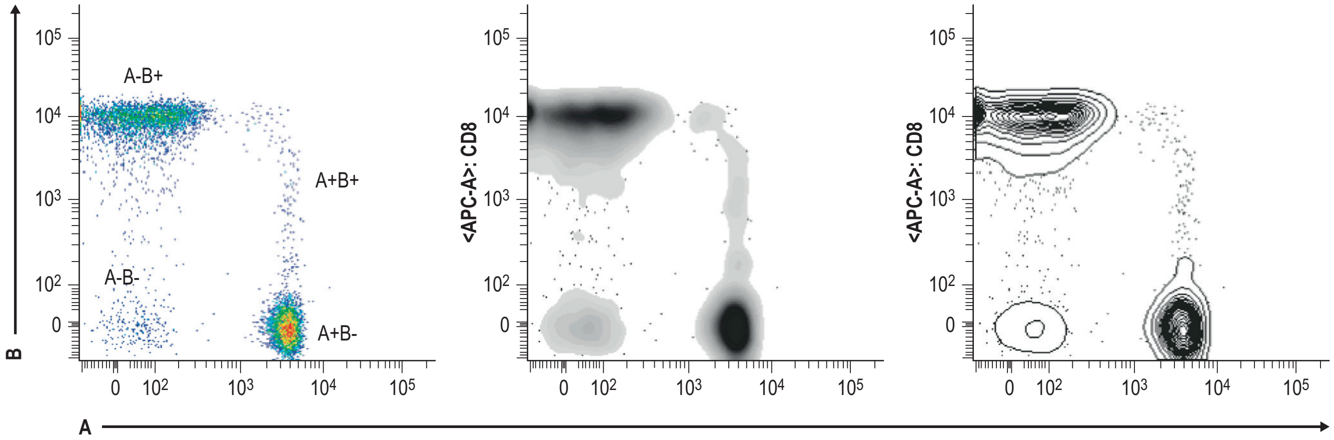

FIG 92.4 Examples of Dot Pseudocolor *(Left),* Density *(Middle),* and Contour *(Right)* Displays Based on the Same Two-Color Parameter Data. All three techniques enable simultaneous evaluation of both parameters, in this case evaluating the expression of markers A and B. These plots identify four populations of cells, those expressing only A or B, those expressing both A and B (very few), and those expressing neither A nor B.

cells and positive (specifically stained) cells. A commonly used approach involves using directly conjugated control mAbs of the appropriate class or subclass (*e.g.*, IgG1, IgG2a, IgG2b, or IgM) that do not specifically react with human lymphocyte surface antigens (commonly referred to as "isotype controls"). The marker (discriminator) is set at the fluorescence histogram channel number such that it includes 98–99% of the negative cells (Fig. 92.5A).

As previously noted, *negative* refers to the aggregate of baseline cellular autofluorescence plus nonspecific reagent binding, and this can vary according to the cell type. For this reason, the use of isotype controls may not correctly identify the positive–negative threshold for specific cell types, particularly when staining dimly expressed proteins. Additionally, to perfectly mimic the specific antibody used, the isotype control would need to have the same antibody to fluorochrome ratio and brightness, something that is not easily accomplished. To overcome these difficulties, an alternative method for positive–negative discrimination, fluorescence-minus-one (FMO), has been developed.[18]

FMO involves the staining of the sample with all the antibodies of interest, except the one targeted for positive–negative threshold. As an example, to define the negative threshold for the protein FAS (CD95) in $CD8^+$ and $CD8^-$ T cells, the FMO control tube would include the cell subset-specific markers (CD3, TCRαβ, and CD8) and omit anti-FAS. After appropriate gating on that population, the threshold can be adequately defined, and it is different for the two exemplified populations (see Fig. 92.5B, *right panel*). One obvious limitation of this method is the higher cost, given that multiple control tubes need to be set up for each sample.

Compensation

The fluorescence signals emitted by different fluorochromes are not completely separated by the filters. This can lead to signal overlap, which is corrected by electronic subtraction of the overlapping signal, a process referred to as *compensation.* The overlap is particularly significant when using multiple fluorochromes, each with different spectral properties.[18] The compensation process involves subtraction of the "spillover" signal detected by the photodetector generated by samples stained with only one fluorochrome. Currently, most flow cytometry analysis software products allow for off-line compensation, where the single reagent stained tubes are used to create a compensation matrix, which is then applied to all the tubes in the experiment. This allows for much simplified compensation procedures, without the need for any hardware compensation during data collection.

Quality Control

Quality control is a critical component of clinical flow cytometry to ensure optimal results.[19] This includes monitoring instrument setup and performance, optimizing sample preparation and reagents, and standardizing controls and data interpretation. Quantitative flow cytometry based on a fluorescence standard curve provides quantitative data in units referred to as *molecular equivalents of soluble fluorochrome* (MESF). When properly constructed standard curves are used, quantitative data for different reagents can be generated and compared. Finally, participation in interlaboratory proficiency testing surveys, such as the triannual samples provided by the College of American Pathologists (CAP), is an important additional measure to monitor laboratory performance, and this is mandated in US clinical laboratories by the Clinical Laboratory Improvement Amendment of 1988 (CLIA 88).

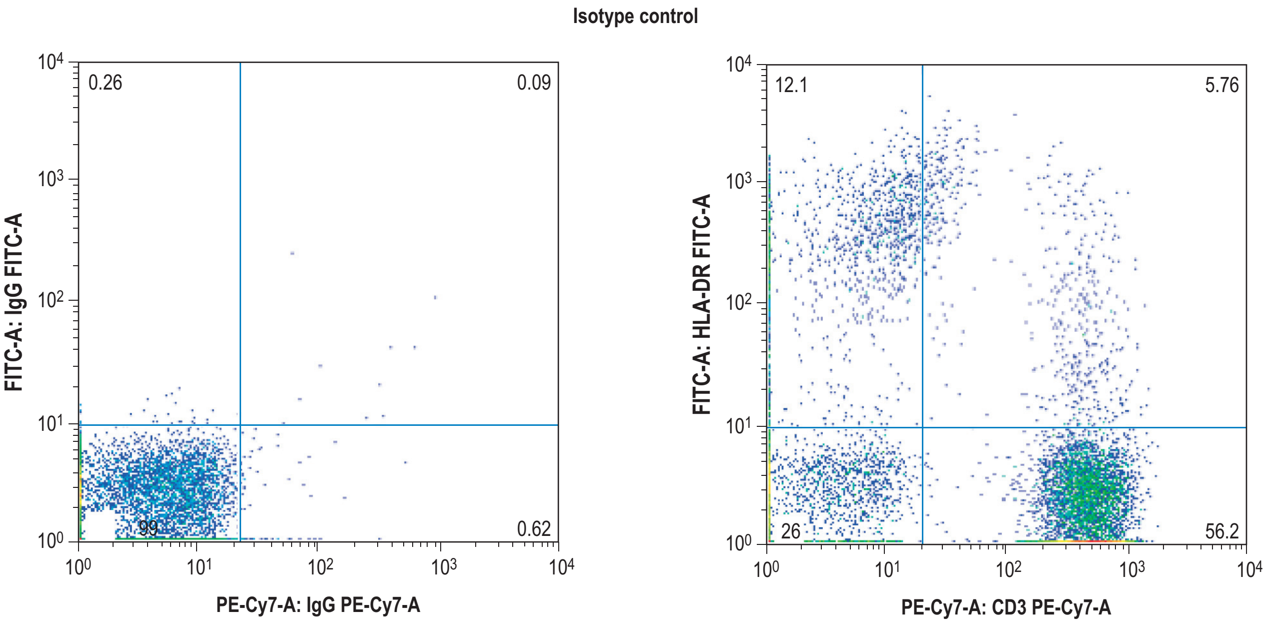
Methods

Whole-blood lysis represents the most common technique used for sample preparation and consists of mixing a fixed volume of anticoagulated whole blood (or bone marrow) with one or more directly conjugated mAbs, followed by incubation at a designated temperature and time.[20] Next, RBCs are lysed, and the sample is washed and then run into the flow cytometer, usually following fixation in paraformaldehyde to reduce the risk of infection. Nonlysed cells that remain include all peripheral blood leukocytes as well as any nonlysed RBCs, platelets, and debris. The heterogeneity of the sample necessitates careful lymphocyte gating (see Gating section above) to generate accurate immunophenotyping data. The advantages of the whole-blood-lysis method include fewer preparation steps, less sample handling, and a lower likelihood of differential lymphocyte loss that can occur when density gradient techniques are used to prepare mononuclear cells for analysis. Alternative sources of cells (*e.g.*, bone marrow, bronchial alveolar lavage fluid, fine-needle aspirates) can also be evaluated with flow cytometry.[21] Patient studies must be determined with the same methods and reagents as used in the determination of the control ranges to ensure comparability. The number of events (cells) analyzed typically ranges from 10 000–20 000 in routine clinical studies but must be increased when evaluating very small subpopulations of cells to produce statistically relevant data necessary in rare-event analysis.

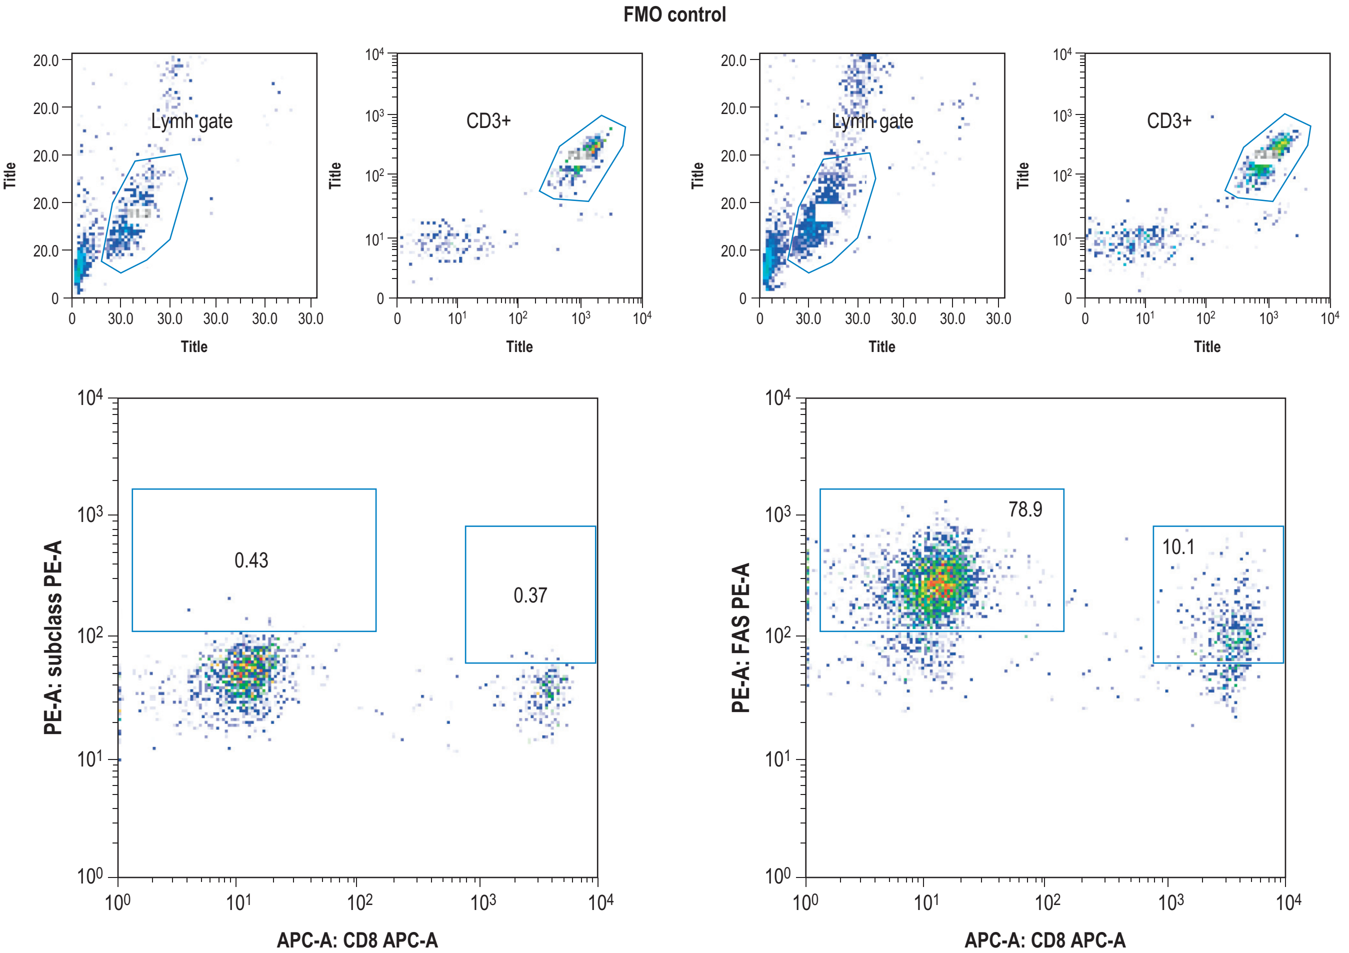
The application of control ranges must take into account the fact that significant changes take place in lymphocyte distribution and development during childhood, as well as changes in lymphocytes that occur among the very old.[22,23] In addition, since immunophenotypic differences can be induced by drugs, including tobacco products, information on current medications should be obtained, whenever possible. Other factors can also have an impact on lymphocyte distribution, including race, gender, diurnal variation, and recent or intercurrent infections.[24]

The choice of immunophenotyping reagents depends on the cells being targeted for study and the question being asked. However, regardless of the specific setup, the inclusion of a tube with gating reagents (anti-CD45 and anti-CD14) to confirm the integrity of the standard lymphocyte gate is recommended.[13] In addition, control reagents should be included to establish the fluorescence intensity of negative cells. Important internal controls include a pan-T-, B-, and natural killer (NK)-cell marker for every sample (Table 92.1), based on the principle that the whole is the sum of its parts. Thus the total percentage of lymphocytes in the gate determined by the gating reagents should approximately equal the sum of the percentages for T, B, and NK cells. A technical or biological explanation must be identified when this relationship does not hold. Biological explanations for a significant difference would include the presence of immature or malignant cells that were not identified by standard pan-T-, B-, and NK-cell reagents. Also, if the gating reagents (CD45/CD14) had not been included, contaminating cells (*e.g.*, myeloid precursors, nucleated RBCs, large platelets) with FSC and SSC characteristics similar to those of lymphocytes could not be ruled out. Potential technical problems include reagent or fluorochrome degradation, failure to add a reagent, and a host of others. Evidence for any major technical error should result in repeating the study.

Additional data that can be used for controls depend on the setup. For example, the availability of multiple antibodies that



Isotype control



FMO control

FIG 92.5 **Positive–Negative Discrimination Strategies.** (A) Nonspecific antibodies (isotypes) were used to stain the sample shown on left and the positivity threshold determined and applied to the sample on the right. (B) Fluorescence-minus-one (FMO). The positivity threshold was determined by staining the sample on the left with the population-specific markers (CD3, TCRαβ, and CD8) and omitting FAS. The panel on the right contains FAS. Note that the positivity threshold is slightly different for $CD8^+$ and $CD8^-$ cells.

TABLE 92.1 Selected Lymphocyte Surface Antigens for Immunophenotyping

T Cells

Pan-T cell: CD3, CD2, CD7, CD5
Major T-cell subset: CD4, CD8
Surface antigens associated with function: CD28, CD31, CD38, CD45RA, CD45RO, CD62L, CXCR7
Activation antigens: CD25, CD40L, CD69, CD71, HLA-DR

B Cells

Pan-B cell: CD19, CD20, surface immunoglobulin
Major B-cell subset: CD5, CD21
Surface antigens associated with function: CD27, CD40, CD80, CD86
Activation antigens: CD23, CD25

NK Cells

Pan-natural killer (NK) cell: CD16, CD56
NK subset: CD2, CD8, CD57

identify a similar cell subpopulation can serve as a useful check (*e.g.*, total T cells by comparing CD3 and CD5 or CD2; total B cells by comparing CD19 and CD20). In addition, the use of specific reagents in >1 tube enables comparison between the repeat values as a measure of consistency. The application of internal checks should be performed by the flow operator as a simple means of confirming the validity of the data. Insights regarding unusual biological findings may also be uncovered through this type of evaluation (*e.g.*, the presence of an increased population of $CD4^-$/$CD8^-$ double-negative T cells).[25]

The challenge in performing immunophenotyping is to accurately identify cells with specific surface characteristics (antigens). As previously noted, the capacity to discriminate cell subpopulations is often enhanced through the directed use of antibody combinations. The typical data generated consist of the percentage of negative versus positive cells when using one reagent and multiple subpopulations when using more than one reagent. Regardless of the experimental design, it is important to consider not only the percentage of cells within each subpopulation but also the absolute number of cells. This is most commonly obtained by multiplying the relevant percentage from the flow cytometer by the absolute lymphocyte count obtained by using a white blood cell (WBC) count and differential. For example, when assaying for CD4 T-cell counts, the percentage of $CD4^+$ cells is multiplied by the peripheral absolute lymphocyte count to yield the absolute CD4 count. A potential problem with this approach is the requirement for two separate procedures (*i.e.*, dual platforms) to generate the final result. This introduces the possibility of additive error, based on the inherent errors of the two different methods. It also has fueled a search for approaches that facilitate performing both tasks by flow cytometry (*i.e.*, a single platform). One alternative involves the inclusion of a fixed number of fluorescent beads (in a defined volume) in each tube as a reference standard to generate absolute numbers without requiring the use of the complete blood count (CBC) and differential to generate a lymphocyte count. An alternative approach involves the use of impedance-based cell counting in the flow cytometer to generate an absolute lymphocyte count (dependent on a fixed volume of sample being run) and then generating both percentage and absolute number of cells in each specific population or subpopulation. Regardless of the approach, the reporting of both percentages and absolute numbers is necessary when immunophenotyping peripheral lymphocytes.

The objective of evaluating malignant cells is often to characterize the lineage and differentiation level of the abnormal cells, rather than quantifying subpopulations. The pattern of reactivity combined with fluorescence intensity is often useful in identifying leukemic patterns, whereas the absolute number of cells usually is not required. However, flow-cytometric detection and quantitation of rare abnormal cells can be useful in evaluating for minimal residual disease after therapy in lymphoproliferative disorders.

PRACTICAL APPLICATIONS OF FLOW CYTOMETRY

Immunophenotyping Studies

CLINICAL RELEVANCE

Immunophenotyping Studies

- Immunotyping studies can be used to identify cell subsets, lineage, stage of cell differentiation, state of cell activation, and clonality.
- Lymphocyte results should be checked with T cells + B cells + natural killer (NK) cells = 100%.
- Immunophenotyping studies are not the equivalent of lymphocyte function studies.

Most immunophenotyping studies aim to enumerate specific cell subpopulations, evaluate for the presence or absence of particular surface antigens, identify the differentiation level of specific cells, determine cell lineage, evaluate for functional correlates based on specific antigen expression, examine evidence of cell activation, and/or establish evidence of monoclonality.

Quantification of a particular cell subpopulation can be readily accomplished by flow cytometry together with a WBC count and cell differential. The absolute lymphocyte count is used to generate population or subpopulation cell numbers based on the percentages of the respective cell types generated with the flow cytometer. The evaluation of absolute CD4 T-cell counts has formed the basis for monitoring patients with HIV infection.[26] The quantitation of $CD34^+$ hematopoietic stem cells (HSCs) in donor peripheral blood or bone marrow is used in many cellular reconstitution protocols.[27] Subpopulation characterization can also be useful in the evaluation of patients with clinical history and laboratory findings suggestive of immune deficiency.[28] This has taken on a higher level of significance in the setting of newborn screening for severe T-cell immune deficiency via the T-cell receptor excision circle (TREC) assay, which, when abnormal, is typically followed by immunophenotyping to evaluate for naïve T cells based on CD45RA, CD127, or CD62L expression.

When evaluating for the presence or absence of surface proteins associated with specific functional attributes, it is important to realize that this approach does not assess the actual functional status of cells. This point is clearly illustrated by the finding of normal B-cell numbers in most patients with common variable immune deficiency despite the fact that these patients fail to produce Igs normally.[29] However, changes in the characteristics of the B cells, particularly relative to memory B cells, provides potential insight into different phenotypes of this disorder and provides additional support for heterogeneity of patients with the disease.[29-31] Because of the limitations of immunophenotyping, when evaluating the status of the immune system, it is common practice to perform cell function testing in parallel.

Flow cytometry can be used to test for the presence or absence of a specific cell surface antigen. An example of this type of application is in the evaluation of a patient with a history of recurrent skin infections, delayed wound healing, and persistent granulocytosis, which suggests a diagnosis of leukocyte adhesion deficiency type 1 (LAD-1).[28,32] This disorder results from a defect in the gene encoding CD18, preventing the expression of three different heterodimeric adhesion molecules (β_2 integrins) each containing CD18 (Chapter 22). This disorder can usually be diagnosed by studying granulocytes (and lymphocytes) for the expression of CD18 (as well as the three isoforms of CD11). Patients often have decreased rather than absent CD18 expression and confirmation of the diagnosis can be accomplished by demonstrating failure of CD18 (and CD11a, 11b, 11c) upregulation following granulocyte activation.[28]

Immunophenotyping can also help address questions regarding the level of cell differentiation. Antibodies specific to proteins expressed by early (precursor) cells represent one approach and would include evaluating for the thymocyte marker CD1 or the pre-B-cell marker CD10 (CALLA), to cite a few. However, defining the developmental level of a particular cell population or subpopulation is best accomplished by using a panel of reagents that span the natural history of the cell lineage. This approach represents the standard for testing leukemias and lymphomas. In addition to defining the presence or absence of specific antigens, evaluating their level of expression is also valuable, which may be altered in abnormal cells. Malignant cells may also express antigens associated with different lineages and have altered FSC and SSC characteristics, as well as diminished or absent CD45 expression, requiring modified gating approaches.

Issues of monoclonality can be dealt with by using flow cytometry when analyzing B cells and, in some circumstances, when studying T cells. Normally, B cells are a heterogeneous mixture of mutually exclusive κ or λ light-chain-positive cells. Measuring the distribution of κ or λ light-chain-expressing B cells or plasmocytes can be informative with respect to the presence or absence of monoclonality.[33] The capacity to evaluate T-cell monoclonality by flow cytometry is less definitive and consists of using T-cell antigen receptor β-variable (Vβ) chain-specific reagents looking for evidence of significant overrepresentation of one Vβ chain family. This approach currently consists of setting up a series of tubes, each with three different Vβ family–specific mAbs, one conjugated with FITC, one with PE, and the third with FITC plus PE. This combination enables distinguishing the frequency of each of the three different Vβ families per tube (green$^+$, orange$^+$, green$^+$/orange$^+$) and represents a flow-cytometric method to complement polymerase chain reaction (PCR)–based spectratyping.[34]

The state of lymphocyte activation can be addressed by evaluating for the presence of surface antigens that are found only on activated cells or are upregulated following activation. These include receptors for specific growth factors (*e.g.,* interleukin-2 [IL-2] receptor α chain, CD25), receptors for critical elements required for cell growth (*e.g.,* transferrin receptor, CD71), ligands for cell–cell communication following activation (CD40 ligand [CD152] on activated CD4 T cells), and surface antigens that are upregulated as a result of activation (*e.g.,* adhesion molecules, HLA-DR, CD69). In addition, the memory status of both T cells and B cells can be assessed on the basis of differential surface molecule expression associated with prior antigen encounter. This enables a distinction to be made between naïve T cells that express CD45RA, CD31 (recent thymic emigrants), CD62L, and CXCR7 and memory T cells that express the alternative CD45 isoform, CD45RO (and varied CD62L, or CXCR7, depending on whether the cells are central or effector memory cells).[35] In addition, memory B cells can be detected by the expression of CD27 and can be further divided into isotype-switched and isotype-nonswitched memory cells on the basis of their pattern of surface immunoglobulin expression.[29,36]

Defects associated with familial lymphohistiocytosis (FLH) are generally associated with abnormal NK cell function. Many of the FHL-causing defects can be determined by flow cytometry. For example, signaling lymphocyte activation molecule (SLAM) associated protein (SAP) and X-linked inhibitor of apoptosis (XIAP) intracellular staining can be used to evaluate for X-linked lymphoproliferative (XLP) disorders types 1 and 2, respectively. Likewise, lack of intracellular perforin expression in NK cells would be indicative of hemophagocytic lymphohistiocytosis (HLH) type 2. Additionally, the evaluation of CD107a surface expression, which is normally expressed on cytoplasmic granules and upon incubation with specific target cells (*e.g.,* K562 cells) gets expressed on the surface of NK cells, is useful in determining the underlying genetic defect causing FHL.[37,38] Specifically, lack of CD107a upregulation is suggestive of syntaxin-11 or MUNC-13.4 defects.

INTRACELLULAR EVALUATION

Cellular Activation

CLINICAL RELEVANCE

Intracellular Flow Cytometry

- Activation-directed studies:
    - Calcium flux
    - Intracellular protein phosphorylation
    - Oxidative burst: neutrophils
- Intracellular cytokine studies:
    - Clarify the T-helper-1 (Th1)/Th2/Th17 status of an immune response
    - Can be assessed in an *in vitro* antigen-specific response
    - Can be combined with evaluation of cell surface studies

Ligand binding and transmembrane signal transduction resulting in cellular activation can be evaluated by using flow cytometry. Changes in intracellular ionic calcium concentration (Ca^{2+}) can be used to monitor cell activation after ligand binding. These changes are associated with the activation of phospholipase C and protein kinase C. In general, three reagents have been used to measure Ca^{2+}: quin 2, indo-1, and fluo-3. Quin 2 has a low excitation coefficient and is not useful for flow cytometry; indo-1 requires ultraviolet excitation; fluo-3 can be excited by 488 nm but does not permit ratiometric analysis. Nevertheless, because of its ease of use, fluo-3 is currently the most widely used probe for intracytoplasmic Ca^{2+} evaluation by flow cytometry. Strict attention must be paid to loading conditions, the presence or absence of free Ca^{2+} in the medium, experimental temperature, baseline measurements, and calibration. This approach can be combined with cell surface marker or cell cycle evaluation.[10]

Intracellular pH changes related to cellular activation also can be evaluated. The most useful probe for pH is SNARF-1.[10] This probe can be excited at 488 nm and allows for ratiometric analysis with detection wavelengths set for 575 and 640 nm. Glutathione (glutamylcysteinylglycine [GSH]), an important antioxidant generated during cell activation, that can be measured by using flow cytometry.[10] The fluorescent probe monochlorobimane is commonly used for this measurement, but it is complicated by the need to determine GSH by an independent method, such as high-performance liquid chromatography (HPLC).

Additional approaches for evaluation of cellular activation include assessment of intranuclear markers (Ki-67, PCNA) as well as surface proteins that are upregulated following cellular activation (*e.g.,* CD69, CD25, CD71).[39] Actual cell division can be evaluated by using lipophilic membrane dyes (*e.g.,* PKH26, CFSE, Cell Trace Violet), also referred to as *cell tracking dyes,* which lose 50% of their fluorescence with each round of cell division.[40] This approach has become more common in the clinical assessment of lymphocyte function because of the capacity to evaluate specific lymphocyte subpopulations responding to mitogenic and antigenic stimuli. Lipophilic membrane dyes also can be used to label target cells in cell-based cytotoxicity assays.[41] Recently, an approach to evaluate lymphocyte proliferation following cell stimulation has been described by using the modified nucleoside EdU. Detection of DNA synthesis induced by the different activating agents is measured using a copper-catalyzed click chemistry, which results in EdU being covalently bonded to a fluorescent azide.[42] This approach allows for assessment of cell proliferation at the cell population or subpopulation (*e.g.,* CD3, CD4, CD8) level and can be used in association with mitogen and recall-antigen stimulation.

Functional evaluation of cell activation can be accomplished with flow cytometry–directed detection of the generation of phosphorylated intracellular proteins associated with specific activation signals. An example of this is the detection of phosphorylated signal transducer and activator of transcription 1 (STAT1) following interferon-γ (IFN-γ) stimulation of monocytes, which has been found to be equal to or more sensitive than immunoblotting.[43] This type of assay requires fixation and permeabilization to allow entry of the specific reagent and now has been extended to a number of additional intracellular proteins that are phosphorylated following exposure of selected cells to specific stimuli. Currently, a number of intracellular signaling proteins that undergo phosphorylation following a specific activation signal can be assessed with flow cytometry by using commercially available reagents, some of which are offered in kit form.

The assessment of oxidative burst following cell stimulation plays a central role in neutrophil function testing where the hydrogen peroxide-sensitive dye DHR123 is used. This procedure involves loading granulocytes with the dye, stimulating with phorbol myristate acetate (PMA), and evaluating for fluorescence with flow cytometry.[11,44] This test has proven to be extremely accurate in diagnosing patients with chronic granulomatous disease (CGD) and carriers of X-linked CGD.[44] A major advantage is its sensitivity, which allows for detection of one normal cell in a population of 1000 abnormal cells. This makes assessment of oxidative burst a useful tool in monitoring allogeneic granulocyte survival after transfusion into patients with CGD, as well as a means of following donor chimerism in the setting of allogeneic stem cell transplantation. It also provides a method to identify corrected cells following gene therapy in CGD and has utility in predicting outcome.[45,46]

Intracellular Cytokine Detection

Flow cytometry affords a platform to evaluate cytokine production at the single-cell level by using cytokine-specific, directly conjugated mAbs after fixation and permeabilization of cells.[47] This approach allows for simultaneous detection of two or more intracellular cytokines in combination with cell surface markers or other intracellular markers. Important aspects of intracellular cytokine detection include use of a protein transport inhibitor during activation, use of proper controls, and choice of antibodies. As there is little or no spontaneous cytokine production in circulating human lymphocytes, intracellular cytokine detection requires *in vitro* activation. Initial experience was based on supraphysiological stimulation with use of PMA and ionomycin, but antigen-specific activation systems have also proven to be feasible. It should be emphasized that regardless of the activation method, the duration of activation is an important variable, as individual cells reach maximum cytokine production at different times. In addition, different cytokines have different optimal periods of activation. It is recommended that a proper kinetic profile be established for the biological system or clinical condition being studied.[47]

To increase the amount of intracellular cytokines, inhibitors of intracellular protein transport (*e.g.,* monensin or brefeldin) are commonly used, which leads to accumulation of proteins within the cell. Nonspecific binding of antibody reagents is an issue, as permeabilization allows access not only to the cytokine of interest but also to other proteins present in much greater quantities within the cell than on the cell surface. In addition, fixation further increases nonspecific binding, and use of a negative-control sample, which contains an excess of unlabeled or "cold" anticytokine antibody, as well as a subclass-matched or FMO-control sample provides optimal control. When the conjugated anticytokine is added to the negative-control sample, it can only bind to other proteins in a nonspecific manner, thereby providing a measure to discriminate between specific and nonspecific binding. The use of directly conjugated anticytokine antibodies not only simplifies the staining procedure but also provides the best distinction between specific and nonspecific binding. Because the fixation agent may change the native state of certain epitopes, it is also important to use antibodies that recognize antigens after fixation when combining cell surface characterization with intracellular cytokine evaluation.

One of the main applications of intracellular cytokine detection by flow cytometry has been the study and refinement of the T-helper (Th)1/Th2/Th17 paradigms. It has recently become clear that the regulated secretion of cytokines can be used to study the response of individual T cells to both polyclonal stimuli and specific antigens. Measuring antigen-specific T-cell cytokine expression in response to specific antigen offers a useful alternative to the multimer-based approach (discussed below) to quantify the frequency of antigen-specific T cells (Fig. 92.6).[48]

Cell Cycle Analysis

CLINICAL RELEVANCE

Cell Cycle Analysis

- Useful for screening percentage of S phase and aneuploidy
- Can be combined with cell surface studies
- Can be combined with markers of apoptosis

In addition to surface immunophenotyping and cytoplasmic characterization, flow cytometry is also used in cell cycle analysis. PI is the most commonly used fluorochrome because of its optimal linear DNA-binding capacity in a variety of different

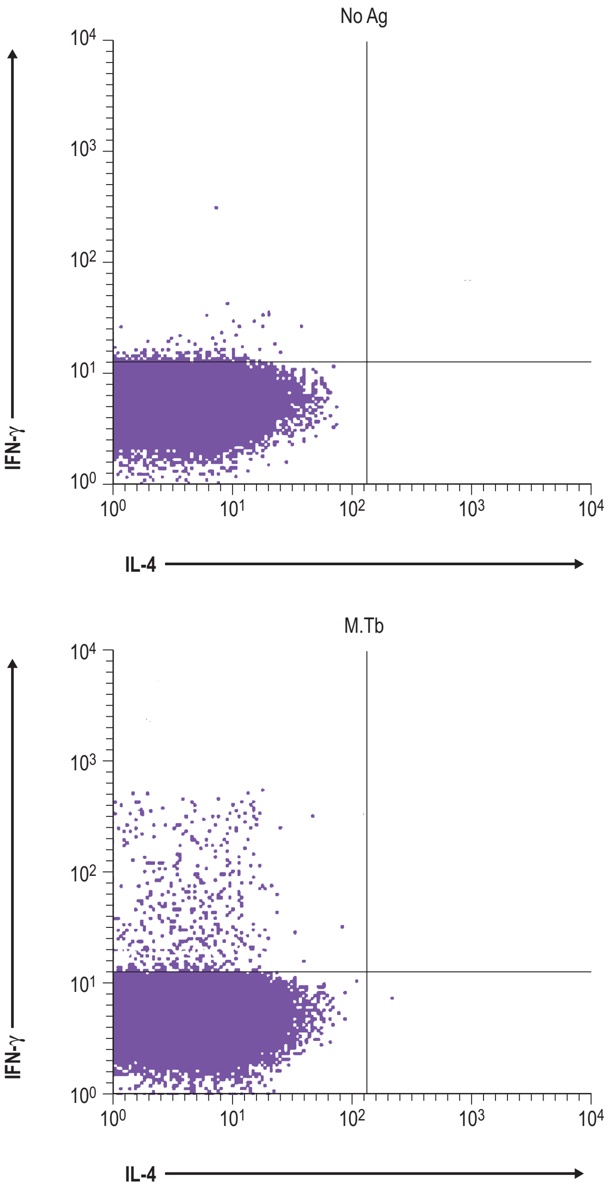


FIG 92.6 Two-color dot plots of CD3$^+$ T cells evaluated for intracytoplasmic interferon (IFN)-γ and interleukin (IL)-4 expression. The donor had a positive skin test to purified protein derivative (PPD) and demonstrated a T-helper-1 (Th1) pattern of cytokine expression (IFN-γ) in response to *Mycobacterium tuberculosis* antigen, with an absence of a Th2 cytokine pattern (IL-4). (Courtesy of Calman Prussin, MD.)

cell types. Thus a single-parameter histogram of DNA content using PI readily permits the determination of cell cycle compartments, expressed as the percentage of cells in G_0–G_1, S, and G_2–M (Fig. 92.7A). In addition to these conventional parameters, the presence or absence of aneuploidy can be determined by inspection of the G_0–G_1 peak and/or use of a DNA index (ratio of abnormal DNA content to a diploid DNA standard). Also, elevation in the S and/or G_2–M phase can be detected. The optimal display of these data uses a combination of SSC versus DNA content. Cells observed on the histogram in the area below the level of G_0–G_1 may be undergoing apoptosis.[49] When dealing with DNA staining, a consistent cellular source of DNA (*e.g.*, chicken erythrocytes) should be used as an internal reference for evaluating DNA content and evaluating the cell cycle distribution.

It should be noted that several different computer algorithms have been developed to determine the relative proportion of each cell cycle compartment, and the selection of a software program is not a trivial process. The major instrument manufacturers supply cell cycle analysis programs, and third-party programs are also available. Generally, the optimal program should be capable of modeling two or more aneuploid populations, subtracting debris (particularly if formalin-fixed, paraffin-embedded [FFPE] archival material is used) and accurately estimating S-phase cells.[49,50] The combination of a surface marker and the cell cycle has been very useful in differentiating normal cell populations from tumor cell populations. One example is the use of anti-κ-, anti-λ-, or B-cell reagents to separate the aneuploid B-cell clone from the remaining normal, reactive B cells in a lymphoid cell mixture. Another uses cytokeratin as a marker to distinguish between tumor cells and inflammatory cells.

The other major event that has occurred in cell cycle analysis has been the development of technology using the incorporation of bromodeoxyuridine.[51] This thymidine analogue is used to directly determine the percentage of S-phase cells. Additionally, when used in kinetic studies, it permits determination of individual times for the components of the cell cycle and determination of the growth fraction. Finally, recent developments have resulted in the availability of two anticyclin reagents to evaluate cell cycle transition points in malignant cells.[52]

APOPTOSIS DETECTION

Flow cytometry has become the method of choice for the detection and quantification of cellular apoptosis,[53] in part because of its capacity for rapid assessment of a large number of cells and samples. Many distinct features of an apoptotic cell can be evaluated by using flow cytometry based on light scatter, plasma membrane changes, mitochondrial transmembrane potential, DNA content, and DNA integrity.

The light scattering properties of a cell undergoing programmed cell death are the simplest attributes that can be assessed by flow cytometry. Dying cells typically shrink, producing a loss in FSC and, despite an initial transient increase in SSC, ultimately demonstrate a decrease in SSC (see Fig. 92.7B). The use of light scatter can be combined with cell surface staining to help characterize the dying cells. However, scatter changes alone are not specific to apoptosis and should be accompanied by an additional characteristic associated with cell death. Live cells have phospholipids asymmetrically distributed in inner and outer plasma membranes, with phosphatidylcholine and sphingomyelin on the outer surface and phosphatidylserine (PS) on the inner side. Early during apoptosis cells lose asymmetry, exposing PS on the outside. Annexin V is a protein that binds preferentially to negatively charged phospholipids, such as PS, and directly conjugated annexin V is a useful reagent for the specific detection of apoptotic cells.[53]

Another characteristic of plasma membranes associated with live cells is that they exclude charged cationic dyes, such as PI and 7-amino-actinomycin-D (7-AAD). Consequently, only cells in a late stage of apoptosis, with ruptured cell membranes, will take up these dyes. Thus the combined use of cationic dyes (*e.g.*, PI) with annexin V allows for discrimination between live cells

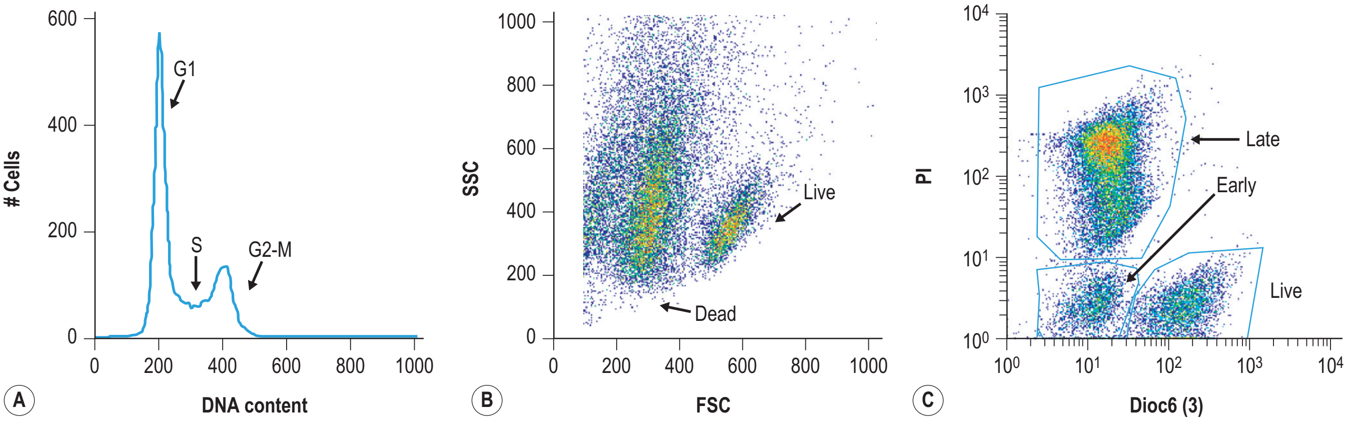

FIG 92.7 (A) Assessment of DNA content as a reflection of cell cycle demonstrating cells in G_1, S, and G_2–M phases. (B) Assessment of live versus dead cells based on forward-(FSC) and side-scatter characteristics (SSC). (C) Assessment of cell apoptosis using propidium iodide (PI) and Dioc6 (3) identifying cells that recently initiated apoptosis (early), cells that are dead (late) and cells that are alive (live).

(annexin V negative/ PI negative), early apoptotic cells (annexin V positive/ PI negative), and late apoptotic cells (annexin V positive/ PI positive).

Assessment of mitochondrial transmembrane potential ($\Delta\psi m$) is yet another technique used to identify apoptotic cells. Cells decrease $\Delta\psi m$ very early in the apoptotic process, before rupture of the plasma membrane, losing the ability to accumulate potential-dependent dyes, such as rhodamine 123, JC-1, or 3,3''-dihexyloxacarbocyanine iodide (Dioc6[3]). These dyes can also be used with PI to detect cells in the different stages of apoptosis (see Fig. 92.7C).

Measurement of DNA content can also be employed to distinguish live cells from dead cells, as described above (see Cell cycle analysis). This kind of analysis has to be done by using a linear scale, not a logarithmic scale, to discriminate dying cells from debris. DNA cleavage also exposes –OH termini associated with the DNA breaks, and these can be detected via the attachment of fluorochrome-conjugated deoxynucleotides, in a reaction catalyzed by exogenous TdT, a technique called *TUNEL*.

PEPTIDE–MHC MULTIMERS

KEY CONCEPTS

Peptide–MHC Tetramers

- Useful for assessing the number of antigen-specific T cells
- Can be directed at both $CD4^+$ and $CD8^+$ T cells
- Requires information about the antigenic peptide and human leukocyte antigen (HLA) (major histocompatibility complex [MHC]) restriction

In contrast to B cells, direct visualization of antigen-specific T cells *ex vivo* has, until recently, been unsuccessful. In 1996, Altman et al. introduced a novel flow cytometry–based methodology that enables the direct visualization and quantification of antigen-specific T cells.[54] Soluble peptide–MHC multimers are generated such that multiple T-cell receptors (TCRs) are engaged at the same time, which means that the avidity of these multimeric ligands for the peptide-specific TCR is greatly increased. The methodology involves engineering a biotinylation recognition sequence on the –COOH terminus of the extracellular domain of one chain of the MHC molecule, which, after combining with a specific antigenic peptide, is bound by avidin or streptavidin. As both avidin and streptavidin have four biotin-binding sites, the result is a tetrameric peptide–MHC complex that serves as a ligand for T cells specific for both the peptide and the MHC. Flow-cytometric detection is achieved by labeling streptavidin with a fluorochrome. The major pitfall of this approach is the need to know the antigen-derived peptide and its HLA restrictions, as well as the HLA type of each subject studied. Since the initial report, an increasing number of tetramer-based studies have been performed. Most have focused on the MHC class I–mediated immune response, in both mice and humans, to a variety of infectious agents, including cytomegalovirus (CMV), HIV, Epstein-Barr virus (EBV), and others. Since the initial description with class I–restricted recognition, detection of antigen-specific CD4 T cells with tetramers of soluble MHC class II molecules and covalently linked peptide has also been reported.[55]

In addition to demonstrating the feasibility of this approach, published studies have provided several new insights into the MHC class I–mediated immune response (Chapter 5). For example, it has become clear that the extent of the MHC class I–mediated cellular response is much greater than previously estimated. Furthermore, the extensive proliferation of CD8 T cells during an acute infection is not the result of bystander activation but represents an expansion of antigen-specific CD8 T cells. Peptide–MHC tetramer assays have shown promise in the study of the kinetics of primary and secondary immune responses and have resulted in better understanding of such concepts as immunodominance and clonal exhaustion.

An obviously attractive aspect of this technology is that tetramer staining can be combined with a variety of cell surface and intracellular phenotypic and functional markers. Indications that the phenotype of antigen-specific T cells varies among individuals and among different phases of the immune response are already present. In addition, tetramer-positive T cells can be sorted for further analysis, such as cytotoxicity assays or *in vitro* expansion. Tetramer-based technology has not only proven useful for the study of the immune response to infectious agents, it has also been applied to the study of oral tolerance, autoimmune conditions, and tumor immunology. It is likely that this highly sensitive and specific technology and other approaches that define the antigen-specific response will find many more applications and will lead to new discoveries and a reassessment of certain existing concepts.[56]

CONCLUSIONS

ON THE HORIZON

- The combination of flow cytometry and mass spectrometry expands the number of cell markers analyzed simultaneously (≥35 currently performed), including extracellular and intracellular targets to provide an extensive evaluation of functional markers.
- Flow cytometry utilizing spectral rather than conventional light analysis has the potential to allow more "colors" to be accurately evaluated without the need for complex compensation schemes to handle the overlapping light emissions from conventional fluorochromes. This could facilitate more extensive polychromatic studies to be performed easily in the clinical laboratory.

Flow cytometry has become readily available in clinical laboratories, and the application of this technology has moved forward along with significant improvements in instrumentation and the availability of an array of monoclonal reagents. Properly performed, flow cytometry can provide rapid and accurate lymphocyte subpopulation identification. The primary clinical indications of immunophenotyping remain quantifying CD4 T-cell counts in HIV infection, lineage assignment in leukemias and lymphomas, evaluation of other hematological cell types, and assessment of CD34 expression to identify stem cells for transplantation. Additional uses include characterization of immune deficiency disorders, evaluation of immune-mediated inflammatory diseases, and assessment of patients after organ transplantation. Generally, immunophenotyping does not represent a diagnostic procedure but, rather, plays a part in the evaluation and understanding of complex disorders and the longitudinal evaluation of immunomodulatory therapy.

It is critical to recognize that immunophenotyping is a means of identifying cells but is not directed at cell function. The expansion of flow-cytometric techniques to evaluate intracellular characteristics, assess intracellular changes associated with activation, characterize apoptosis, and identify antigen-specific T cells has moved this technology into the cell function arena. These newer approaches expand the utility of flow cytometry as a valuable method for the characterization of various aspects of immune function.

MULTIPLE-CHOICE QUESTIONS

1. In flow cytometry compensation refers to a process that:
   A. Distinguishes between leukocyte populations
   B. Eliminates overlapping fluorescent light signals
   C. Provides the level of the cellular autofluorescence
   D. Converts analog light signals into digital signals

2. A flow cytometry setup with a combination of five different monoclonal reagents, each with a different fluorochrome, generates how many potential cell subsets?
   A. 8
   B. 16
   C. 32
   D. 64

3. The finding of a CD3 cell count of 285/mm^3 and no CD4/CD45RA cells in an infant is most consistent with which diagnosis?
   A. Dedicator of cytokinesis 8 (DOCK8) deficiency
   B. CD40 ligand deficiency
   C. Severe combined immunodeficiency
   D. Wiskott-Aldrich syndrome

4. Which test would be indicated in a child with persistent systemic nontuberculous infection not responsive to multiagent antimicrobial drugs?
   A. Dihydrorhodamine (DHR) assay
   B. Expression of CD18 on granulocytes
   C. Level of T-helper-1 (Th1) cell–based on intracellular interferon-γ (IFN-γ) expression
   D. Expression of the IFN-γ receptor type 1 on monocytes

Assessment of Functional Immune Responses in Lymphocytes

Roshini Sarah Abraham

The immune response is mediated by a complex network of cells, soluble and membrane-bound biological mediators and receptors interacting within the context of specific tissues and organs to protect against pathogens. Although the immune system has been broadly divided into innate and adaptive components, there is considerable overlap and interaction between the two, despite the highly specialized functions and kinetics of each in the immune response. T and B cells form the pillar of the adaptive immune response, whereas natural killer (NK) cells are the effector lymphocytes of the innate immune response. There are approximately 2×10^{12} lymphocytes in the body, and typically the response to a foreign antigen is in the context of initial activation of innate immune components. T cells recognize antigen primarily in the context of antigen-specific T-cell receptors (TCRs) and specific peptides presented by molecules of the major histocompatibility complex (MHC), either class I or class II (Chapters 5 and 6). T cells are also capable of responding nonspecifically to polyclonal stimulators, such as mitogens (*in vitro*) or superantigens (*in vivo*) that do not initiate an antigen-specific proliferative response. T cells upon activation also produce cytokines that are crucial to their effector functions including activating B cells and inducing antibody production, promoting differentiation of cytotoxic T cells, activating macrophages, and promoting activation and migration of inflammatory cells. Cytokines play a role in the induction of the T-cell response when produced by antigen-presenting cells (APCs) at the time of antigen recognition. B cells recognize antigen directly via the B-cell receptor (involving surface immunoglobulin) and produce antibodies with help from T cells (T-dependent antigens) or from the innate immune system (T-independent antigens). More recently, the granularity of the antibody response has been further delineated, and T-dependent antibody responses are divided into type 1, with help provided by T-follicular helper cells (Tfhs), and type 2, with help provided by NKTfh cells. Similarly, T-independent responses are classified into three groups: type 1, induced by recognition of microbial antigens by the Toll-like receptors (TLRs) in the absence of Bruton's tyrosine kinase (BTK); type 2, which requires the presence of BTK; and type 3, which has neutrophil B-helper cells.[1,2]

Regulatory (Treg) cells have been shown to play a critical role in the control of both physiological and pathological immune responses in a variety of contexts (Chapter 18). Treg cells exert a direct inhibitory effect on the development of autoimmune disease because their absence leads to the development of a severe phenotype, as manifested by the FOXP3 deficiency, IPEX (immune dysfunction/polyendocrinopathy/enteropathy/X-linked)[3] (Chapter 35). Treg cells can suppress the proliferation of antigen-stimulated naïve T cells, as demonstrated by *in vitro* studies, and induction of FOXP3 in conventional naïve T cells imparts suppressive function *in vitro* and *in vivo,* resulting in the generation of induced-regulatory (iTreg) T cells.[4] Besides producing antibodies to neutralize pathogens as well as presenting antigen to T cells, B cells also exert immunomodulatory control of the immune response, primarily via interleukin (IL)-10 production. IL-10–producing B cells, classified as regulatory B (Breg) cells, play an important role in immune homeostasis and in protection against autoimmune responses and inflammatory damage. Breg cells, in addition to producing IL-10, secrete other cytokines that act on other effector T-cell subsets, Tregs, APCs such as dendritic cells (DCs), and macrophages.

NK cells are considered to be innate immune effector cells, but they straddle the threshold of innate and adaptive immunity. NK cells are directly involved in cytotoxicity and cytokine secretion upon activation, but they also function indirectly by regulating APC and the effector T-cells' response. NK cell activation is controlled by synergistic signals from activating and inhibitory receptors.[5] The characteristics, responses, and assays to measure the activity and function of each of these subsets are described in detail in the sections below.

T-CELL RESPONSE

T cells form the cellular arm of the adaptive immune response, and each T cell has unique specificity derived from the presence of a functional, antigen-recognizing receptor on the cell surface. Naïve T cells derived from the thymus can migrate through the peripheral circulation and secondary lymphoid tissues (spleen and lymph nodes), but they cannot effectively participate in the immune response to pathogens. To do so, naïve T cells must undergo a defined process of cellular activation, which involves recognition of antigen by the TCR in the context of MHC molecules. The majority of circulating T cells express the α/β TCR, whereas a smaller proportion of cells express the γ/δ TCR. On the surface of the T cell, the TCR associates with the CD3 complex, comprised of four distinct subunits (γ, δ, ε, and ζ); the cytosolic components of the CD3 complex are involved in the intracellular propagation of signals after ligation of the TCR. Besides the CD3 complex, the TCR also clusters with a CD4 or CD8 coreceptor, depending on the type of T cell; CD4 T cells recognize antigen (Ag) in the context of MHC class II, whereas CD8 T cells recognize antigen presented on MHC class I. The first signal or "cognate" signal, which is recognition of peptide-MHC complex by the TCR, results in actin-mediated reorganization of the cytoskeleton in both the T cell and APC to form the immunological synapse (Fig. 93.1). The synapse consists of the

FIG 93.1 Schematic of T-Cell Activation. T cells recognize antigen in the context of major histocompatibility complex (MHC) molecules on antigen-presenting cells (APCs). Sustained interaction between a T cell and APC results in the formation of the immunological synapse with membrane reorganization and ordering of key molecules on both cells into a supramolecular activation complex (SMAC) comprised of c (central) SMAC and p (peripheral) SMAC. Cognate interaction with appropriate costimulatory signals results in intracellular signaling events that ultimately result in T-cell activation. TCR along with other costimulatory molecules and adhesion receptors, which results in the formation of a large macromolecular structure called the supramolecular activation complex (SMAC). The unique organization of the SMAC results in prolonged and stronger intracellular interactions and appropriate downstream signaling activity, including phosphorylation of the CD3 receptor components. The complete culmination of the TCR-induced signals results in IL-2 production and secretion, which drives T-cell proliferation in an autocrine and paracrine manner.

It is important to recognize that various T-cell processes and stages of differentiation are specifically regulated by metabolic pathways.[6] For example, naïve T cells rely on oxidative phosphorylation for their metabolism, with additional glycolytic metabolism during times of proliferation. On the other hand, activated effector T cells demonstrate aerobic glycolysis and increased oxidative phosphorylation. T-helper cell-1 (Th1), Th2, and Th17 CD4 effector T cells use glycolytic metabolism, whereas regulatory T-cell and memory T-cell development is enhanced by fatty acid oxidation and catabolic metabolism. In particular, memory T cells are quiescent and mainly use oxidative phosphorylation; however, on antigenic rechallenge, the use of oxidative phosphorylation and glycolysis is rapidly facilitated.[6] While naïve T-cell activation and differentiation into effector cells is essential for a normal immune response during exposure to acute antigenic challenge, chronic antigenic stimulation via persistent antigen exposure and/or inflammation causes an alteration of memory T-cell differentiation, resulting in a state of T-cell exhaustion. During T-cell exhaustion there is a progressive diminution of effector functions, along with upregulation of several inhibitory receptors, metabolic changes, and a failure to transition to a quiescent state and to obtain antigen-independent memory T-cell homeostatic response. Exhausted T cells have only a limited ability to clear pathogens or tumors; however, there is some evidence that this is a reversible phenomenon, at least at a global level.[7]

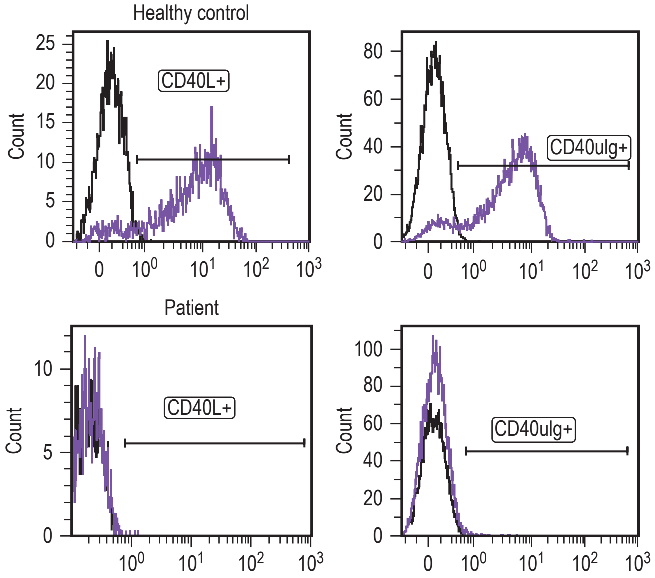

FIG 93.2 Expression of CD40L on Activated CD4 T Cells. CD40L is an early activation marker expressed on CD4 T cells, and it is important for T-cell costimulation and isotype class-switching. In healthy individuals, on T-cell activation CD40L (CD154) is expressed on the cell surface of CD4 T cells and is capable of binding a soluble form of the receptor CD40μIg, which enables assessment of its function *in vitro* (top panel). In patients with X-linked hyper-IgM syndrome due to CD40L deficiency, either there is no protein expression of CD40L on the cell surface and therefore no binding to the soluble receptor (lower panel) or, as is the case with 20% of patients, the CD40L expressed on the cell surface is nonfunctional and cannot bind to the receptor (CD40μIg).

CLINICAL RELEVANCE

Lymphocyte Function Evaluation

- Assessment of lymphocyte function typically refers to measurement of T-cell function via cellular proliferation to nonspecific and specific stimuli; however, it is much broader and more comprehensive and refers to any method that assesses any of the various effector or regulatory aspects of any lymphocyte subset.
- The robustness of clinical interpretation of lymphocyte function assays is dependent on the analytical procedure, sample type, timing of collection, and clinical context, among other factors. Assays performed in clinical diagnostic immunology laboratories are standardized to minimize inconsistencies in these variables.

MEASUREMENT OF T-CELL FUNCTION VIA ACTIVATION MARKERS

Activation of T cells results in the expression of several induced markers, which can be used to ascertain the competence of T cells participating in the immune response. These include CD69, CD154 (CD40L), MHC class II, and CD25, which are expressed in a sequential manner and can be assessed by flow cytometry.[8] In contrast to *in vivo* activation of T cells and subsequent expression of these markers, *in vitro* assessment of T-cell function involves activation of T cells with nonspecific and polyclonal stimulants such as phorbol myristate acetate (PMA) or phytohemagglutinin (PHA), which results in expression of these markers in a kinetically regulated fashion.[8] The expression of CD40L on activated T cells, besides being useful as a global marker for T-cell activation, is used more specifically for the diagnosis of a primary immunodeficiency, X-linked hyper-IgM syndrome or CD40L deficiency (Chapter 35). CD40L on activated CD4 T cells interacts with CD40, expressed constitutively on B cells, and participates in isotype (class)-switching as well as providing costimulatory help to T cells. The expression of CD40L on activated CD4 T cells can easily be ascertained in the laboratory using an *in vitro* T-cell stimulation protocol (Fig. 93.2). In this assay, CD69 is used as a control for early T-cell activation. The majority of patients (80%) with mutations in *CD40LG* have absent protein expression on activated CD4 T cells; however, 20% of mutations may remain permissive for protein expression, but with aberrant function. These patients can be identified by incorporating an additional component in the assay using a soluble form of the receptor CD40-muIg to assess binding of the ligand (Fig. 93.2). The flow cytometric assay for CD40L expression and function offers a rapid diagnostic test for XL-Hyper IgM syndrome[9].

ASSESSMENT OF CELLULAR VIABILITY IN LYMPHOCYTES

The flow cytometry–based assays also allow determination of viable cells in the sample after peripheral blood mononuclear cell (PBMC) isolation from whole heparinized blood, which is particularly important in the interpretation of results (Fig. 93.3). The use of annexin V in a flow cytometry assay enables visualization of apoptotic cells. An early event in cell apoptosis is the translocation of membrane phosphatidylserine (PS) to the cell surface. Annexin V is a calcium (Ca^{2+})-dependent phospholipid-binding protein, which has a strong affinity for PS, and a fluorochrome-conjugated reagent directed at annexin V is used in a flow assay. In addition to visualizing apoptotic cells, dead cells can be assessed by simultaneously using 7-amino-actinomycin-D (7-AAD), which is a membrane-impermeable dye that is generally excluded from viable cells. When internalized into dying or dead cells, it binds to double-stranded DNA by intercalating between base pairs in guanine (G)-cytosine (C)-rich

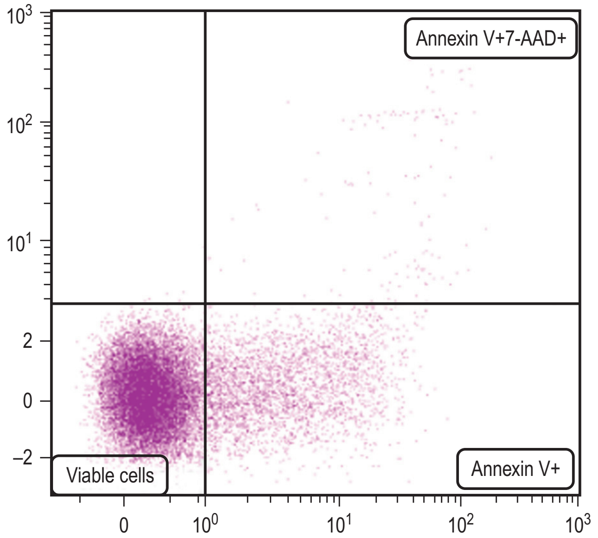

FIG 93.3 Assessment of Cellular Viability for Lymphocyte Function Studies. For all functional assessments of immune response, it is essential and useful to measure the proportion of viable cells at the initiation of the analysis and even at the end of the analysis, if required. Measurement of cell apoptosis and death can be achieved by flow cytometry analysis of annexin V positivity (apoptotic) and annexin V 7-amino-actinomycin-D (7-AAD) dual positive (dead) cells. Cells that are negative for both these markers are viable cells, and their frequency can be assessed in the flow assay.

regions. These two dyes can be combined to provide information on the proportion of viable cells in the starting cell mixture for proliferation assays (Fig. 93.3).

MEASUREMENT OF T-CELL COMPETENCE VIA PROLIFERATION

Mitogens are very potent stimulators of T-cell activation and induce polyclonal T-cell proliferation. It has been suggested that mitogens can induce T-cell proliferative responses even if the lymphocytes are incapable of responding adequately to antigenic (physiological) stimuli. Therefore abnormal T-cell responses to mitogens are considered a diagnostically less sensitive but more specific test of aberrant T-cell function. Lectin mitogens have been shown to bind to the TCR, thereby activating quiescent T cells. Mitogenic stimulation induces increased intracellular calcium (Ca^{2+}) in T cells, which is essential for T-cell proliferation. Whereas PHA is a strong T-cell mitogen (Fig. 93.4), PWM is a weak T-cell mitogen that also induces B-cell activation and proliferation with a different time line for maximal stimulation. Mitogens such as PHA activate T cells by binding to cell membrane glycoproteins, including the TCR-CD3 complex. In addition, there are a number of mitogenic or comitogenic antibodies, including those directed against the CD3 coreceptor that can stimulate T-cell proliferation. Typically, anti-CD3 antibodies provide an initial activation signal and provide a variable proliferative response (Fig. 93.5). Addition of a costimulatory antibody (anti-CD28) to anti-CD3 results in enhanced proliferation (Fig. 93.5). An exogenous T-cell growth factor, such as IL-2, can also be used as an alternate to anti-CD28 costimulation, and in patients with suspected IL-2 receptor (IL-2R)–associated signaling defects, it may be more helpful from a diagnostic perspective than the use of anti-CD28 (Fig. 93.5). IL-2, an autocrine cytokine, has been demonstrated to be critical in T-cell proliferation and in regulation of T-cell growth through binding to a heterotrimeric receptor complex consisting of 3 chains—α, β, and γ (IL-2Rα, IL-2Rβ, and IL-2Rγ)—on the surface of T cells. Triggering of the TCR leads to synthesis of IL-2 in certain T-cell subsets with induction of high-affinity IL-2Rs on antigen- or mitogen-activated T cells; the binding of IL-2 to the IL-2R ultimately leads to T-cell proliferation. The use of exogenous IL-2 in association with anti-CD3 allows discrimination of T cells that cannot proliferate to other mitogenic signals but can respond to a potent growth factor such as IL-2.

KEY CONCEPTS

T-Cell Activation and Function

- Cognate recognition of peptide major histocompatibility complex (MHC) complex on the APC by the T-cell receptor results in formation of the immunological synapse.
- Activated T cells express early activation markers, such as CD69 and CD40L. Other T-cell activation markers include CD25 and MHC class II (human leukocyte antigen–D related [HLA-DR]).
- T cells can be stimulated to proliferate using nonspecific stimulants such as plant lectins (mitogens) and cross-linking of the CD3 coreceptor, along with other costimulatory molecules (*e.g.*, anti-CD28) or in the presence of exogenous interleukin-2 (IL-2).
- The magnitude of antigen-specific T-cell proliferation is dependent on the starting frequency of antigen-specific T cells.
- Flow cytometry–based assays of T-cell proliferation offer the advantages of high resolution, accounting for cellular dilution due to T-cell lymphopenia and single-cell analysis.

Antigens including candida antigen (CA) and tetanus toxoid (TT) have been widely used to measure antigen-specific recall (anamnestic) T-cell responses when assessing cellular immunity. In fact, this may be more revealing about cellular immune compromise than assessing the response of lymphocytes to mitogens because the latter can induce T-cell proliferative responses even if those T cells are incapable of responding adequately to antigenic (physiological) stimuli. Therefore abnormal T-cell responses to antigens are considered a diagnostically more sensitive, but less specific, test of aberrant T-cell function. Antigens used in recall assays measure the ability of T cells bearing specific TCRs to respond to antigenic peptides presented by APCs. The antigens used for assessment of the cellular immune response are selected to represent antigens, seen by a majority of the population either through natural exposure (CA) or as a result of vaccination (TT) (Fig. 93.6).

In addition to measuring cellular proliferation as a readout for T-cell function, the production of cytokines by activated T cells is another important component for evaluating T-cell functional activity. T cells typically are not monofunctional, producing a single cytokine on activation; rather, they are multi- or polyfunctional, and the range of cytokines are produced in a sequential manner rather than simultaneously, although a population of stimulated T cells will have individual T cells producing different cytokines in a temporally regulated manner. These cytokines can be measured by intracellular flow cytometry after T-cell activation with mitogens, in both CD4 and CD8

T-cell subsets or alternatively in the culture supernatant of activated cells. Typically, the cytokines measured in *in vitro* stimulation assays include IL-2, interferon (IFN)-γ, IL-4, IL-5, IL-6, IL-17, and tumor necrosis factor (TNF)-α.

The process of T-cell activation as described above results in IL-2 production that drives T-cell proliferation. Measuring T-cell proliferation after stimulation *in vitro* with various specific and nonspecific stimuli has been a staple of the diagnostic immunology repertoire for several decades. T-cell proliferation assays can be divided into three categories: use of nonspecific mitogenic stimuli such as PHA, pokeweed mitogen (PWM), and concanavalin A (Con A); physiological global stimuli based on CD3 coreceptor cross-linking (using anti-CD3, either soluble or bead-bound) with or without CD28 cross-linking (using anti-CD28, either soluble or bead-bound); and with or without exogenous IL-2. Antigen-specific stimulation depends on the use of common recall antigens.

The commonly used method for assessing T-cell proliferation for decades involved measurement of ^{3}H-thymidine (^{3}H-T) incorporated into the DNA of proliferating cells. The results are expressed as either counts per minute (cpm) or disintegrations per minute (dpm) of both activated and nonactivated cells (background) cultured for a fixed period of time, usually 72 hours for mitogens. A reference range based on proliferation results from a group of control subjects should be provided along with the patients' results (both background and poststimulation results). Although this method remains widely employed, several disadvantages exist, including but not limited to the use of radioactive material (^{3}H-T); its inability to discriminate responder cell subsets or to account for cellular dilution, which is particularly relevant in the context of T-cell lymphopenia; and the lack of information on the contribution of cell death after stimulation and its impact on the final result. To overcome the intrinsic shortcomings of the ^{3}H-T method, newer flow cytometry assays are currently being used in the clinical diagnostic setting and are gaining popularity because of the additional information they provide.

The flow cytometric methods for measuring cell proliferation include the use of fluorescent dyes to identify proliferating cells. One of the more commonly used dyes, carboxyfluorescein diacetate succinimidyl ester (CFSE), must be carefully used when measuring lymphocyte proliferation *in vitro* since it can be toxic to cells and nonoptimal labeling conditions can impact measurement of cell proliferation and interpretation of results. CFSE is a fluorescent cell-membrane permeable dye similar in physical properties to the commonly used fluorochrome, fluorescein isothiocyanate (FITC). During cell proliferation, the intensity of staining in daughter cells is half that of parent cells, allowing visualization of the number of rounds of cell divisions associated with the successive decrease in fluorescence. The disadvantages to using CFSE in the clinical laboratory are its photo-instability, limitation in the number of cell divisions being identified (≤7 cell divisions), and interpretation requires measuring loss of signal rather than gain of signal. In addition, as noted above, CFSE at concentrations of 37 nM to 10 μM can be toxic to cells resulting in increased cell death. Furthermore, it can modulate expression of activation markers, resulting in a decrease in CD69, HLA-DR, and CD25 expression. Finally, it has been reported that there is an increase in the number of false-positive results with CFSE making it suboptimal for measuring lymphocyte proliferation in patients with severe cellular immunodeficiencies. Alternatives to CFSE include related compounds, such as Cell Trace Violet (CTV) and Cell Proliferation Dye eFluor 670 (CPD), which have different excitation and emission spectra compared with CFSE. These dyes also can be used for tracking lymphocyte proliferation status *in vivo,* in animal models, permitting measurement of up to 11 cell divisions.*

Another alternative to tritiated thymidine is the use of a thymidine analog, 5-ethynyl-2′-deoxyuridine (Edu®), which can combine with a fluorescent azide in a copper-catalyzed cycloaddition reaction (referred to as "Click" chemistry) and permits flow cytometric evaluation of lymphocyte proliferative responses by assessing its incorporation into cellular DNA. Edu®- labeling has been shown to be a fast and sensitive method for measuring cell proliferation and also facilitates identification of dividing cells. It is relatively more photo-stable than CFSE and is added to cells after completion of the stimulation period with the measurement being comparable to the thymidine method in regards to a gain of signal is the endpoint. The Edu® assay has not shown the limitations of the CFSE method in the clinical laboratory and has been used to evaluate lymphocyte proliferation in a spectrum of patients, including those with severe combined immunodeficiencies (SCIDs). In fact, this assay has been particularly useful in discriminating between functional T cells and nonfunctional T cells in the context of severe T cell lymphopenia, which cannot be achieved with the standard thymidine assay (Figs. 93.4-93.6). All the proliferation data shown in this chapter utilize this Edu®-based measurement of T cell proliferation, and results are typically provided for both CD45 bright positive (total lymphocytes) and CD3 T cells, with the former being more representative of the data generated with the standard thymidine assay.*

MEASUREMENT OF CELL-MEDIATED CYTOTOXICITY

CD8 T cells are considered the representative cytotoxic T cell in the immune system, and cellular cytotoxicity is a mechanism to eliminate cells infected with intracellular pathogens, allogeneic cells, or tumor cells. CD8 T cells, like CD4 T cells, recognize antigen via the TCR and kill target cells via cytotoxic protein granule exocytosis and/or cytokine production. Over the past few decades, the cytotoxic potential of CD4 T cells has been described, particularly in viral infections. Although cytotoxic CD4 T cells are rare in the circulation of healthy individuals (<2%), they can account for substantial proportions of total CD4 T cells in certain viral infections, including but not limited to HIV.[10] The CD4 cytotoxic T cells appear to be a lineage of memory CD4 T cells that contain cytotoxic granules with perforin and granzymes, and they are thought to arise in the context of chronic or potent activation with viral infections such as cytomegalovirus (CMV), Epstein-Barr virus (EBV), human immunodeficiency virus (HIV), or certain autoimmune diseases.[11]

Cellular cytotoxic activity has been conventionally measured by release of chromium (^{51}Cr) from labeled target (T) cells cultured with various ratios of effector (E) cells (varied E:T ratio). The percentage lysis is developed using the level of radioactivity in the supernatant of target cells in comparison to

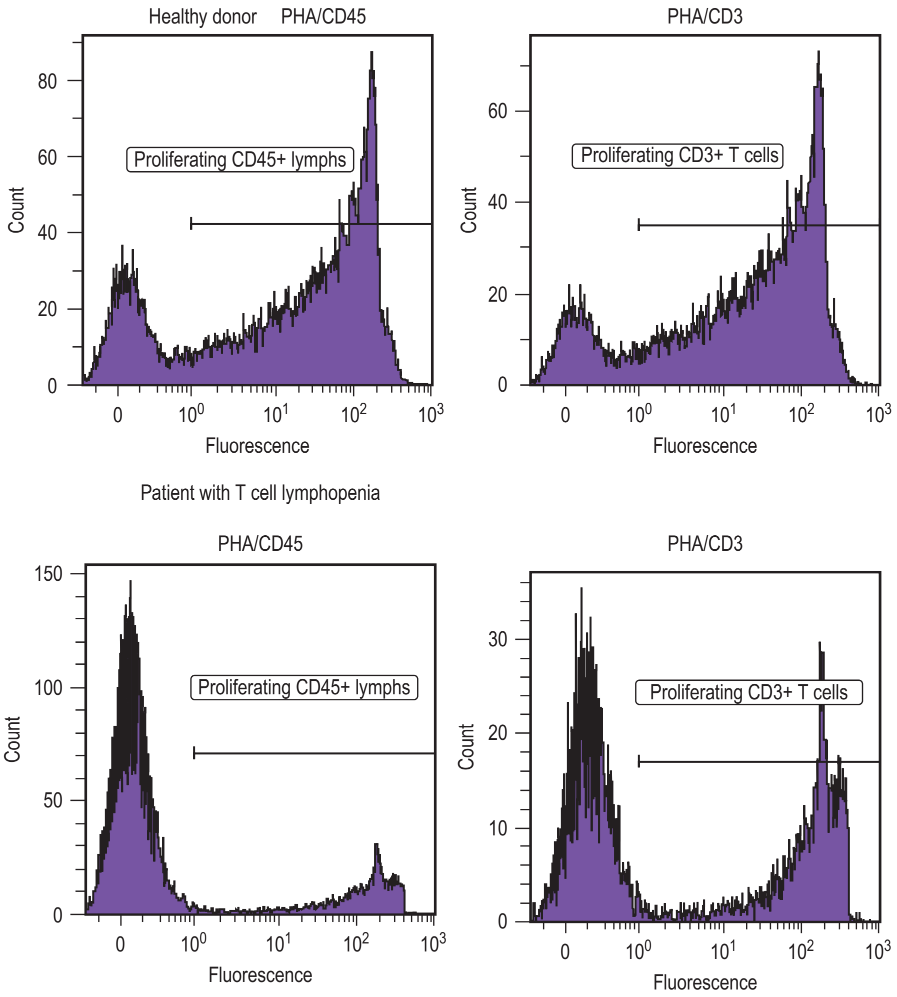

FIG 93.4 T-Cell Proliferation to Mitogenic Stimulants. T cells can respond polyclonally to *in vitro* stimulation with various mitogens. T-cell proliferation assessment by flow cytometry allows analysis in total lymphocytes (CD45$^+$) and T cells (CD3$^+$). The top panel demonstrates T-cell proliferation to phytohemagglutinin (PHA) in both cell subsets. In patients with T-cell lymphopenia, where cellular dilution may be a concern, single-cell analysis by flow cytometry allows discrimination of functional versus nonfunctional T cells. In the lower panel, a patient with T-cell lymphopenia has abnormal proliferation when total lymphocytes are assessed; however, the response is normal when the T-cell compartment is specifically evaluated. Therefore this patient, who would have been classified as abnormal based only on the CD45$^+$ lymphocyte response, can be reclassified as having normal T-cell proliferation based on the CD3$^+$ T-cell response, but with significant T-cell lymphopenia.

KEY CONCEPTS

Cellular Cytotoxicity

- CD8$^+$ T cells and natural killer (NK) cells are involved in killing of cellular targets and contain intracellular granules with cytotoxic proteins, such as perforin and granzymes.
- Cytotoxic CD4$^+$ T cells are a subset of memory T cells with cytolytic potential and are usually observed in circulation in the context of chronic viral infections, *e.g.,* cytomegalovirus (CMV), human immunodeficiency virus (HIV).
- Tetramer-based assays have been used to quantify and delineate function of antigen-specific CD8$^+$ T cells (also CD4$^+$ T cells).
- Cellular degranulation results in expression of CD107a on the cell surface of CD8$^+$ T cells and NK cells and is often used as a surrogate of cytotoxic activity.
- NK cells recognize target cells that lack major histocompatibility complex (MHC) class I, *e.g.,* viral cells or tumor cells that have downregulated MHC class I.
- The majority of circulating NK cells are cytotoxic (CD3$^-$CD16^{++}CD56$^{+/-}$), while a minority are cytokine producing (CD3$^-$CD56^{++}).
- Interleukin (IL)-2 augments NK cell–mediated cytotoxicity (lymphokine-activated killing) and also induces interferon (IFN)-γ secretion by NK cells.
- Regulatory T cells control NK cell activation and cytotoxic function by limiting availability of IL-2.

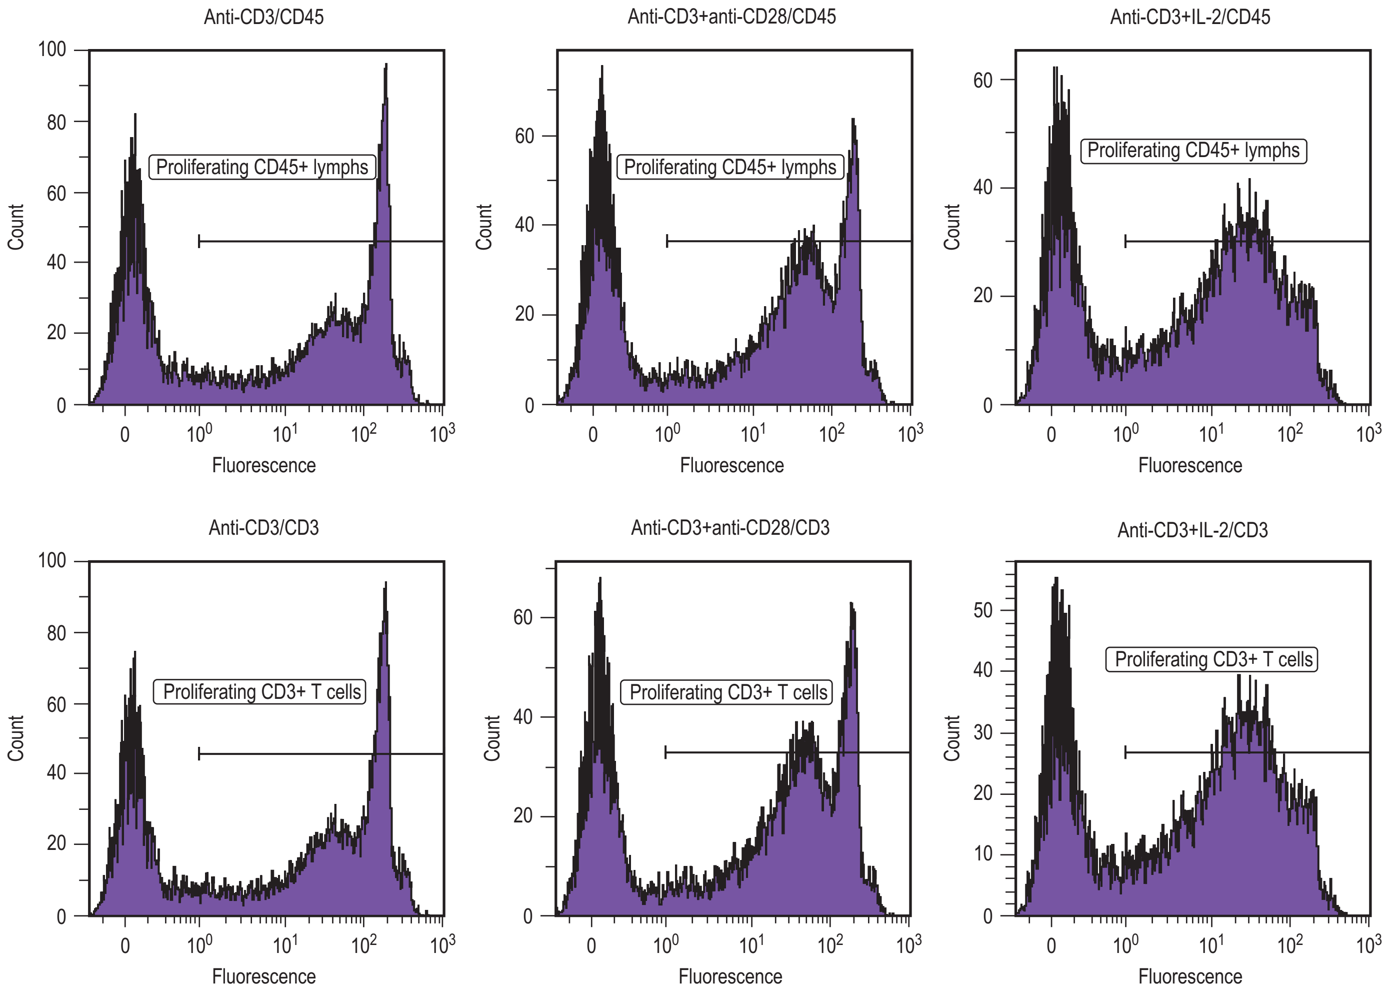

FIG 93.5 **T-Cell Proliferation to Anti-CD3 Stimulants.** Assessment of T-cell proliferation to CD3 coreceptor cross-linking provides a more physiological, yet global, evaluation of T-cell function. T cells are stimulated with either soluble anti-CD3 alone or soluble anti-CD3 plus anti-CD28 or with soluble anti-CD3 plus interleukin (IL)-2. In each case, proliferation is measured in total $CD45^+$ lymphocytes and $CD3^+$ T cells. An example of anti-CD3–stimulated T-cell response is shown in a healthy donor.

controls consisting of target cells cultured alone (no lysis) and target cells exposed to hypotonic conditions (*e.g.*, distilled water, saponin) representing 100% lysis. Similar to the radioactive assay for measuring T-cell proliferation described previously, there are several limitations to the radioactive cytotoxicity assay, including the hazard of radioactive material, the difficulty in labeling target cells with ^{51}Cr, and bulk quantitation of cytotoxic activity, which does not allow single cell–specific analysis. Alternative assays have been developed, including flow cytometry and ELISPOT-based methods.[12] More recently, a method of assessing human CD8 T-cell cytotoxicity has been described in which both the effector and target cells are primary cells (in contrast to using cell lines as target cells).[13] In this particular assay, autologous B cells isolated from PBMC are used as target cells and cocultured with antigen-specific CD8 effector cells. The killing of the fluorescently labeled target B cells (see NK cell section) is used to estimate cytotoxic activity. Antigen-specific effector cells are quantified in the total CD8 T-cell pool using MHC-peptide tetramers.[13]

A tetramer-based approach to quantifying and measuring function of CMV-specific CD8 T cells has been available in the clinical diagnostic immunology laboratory for over a decade (Fig. 93.7). However, the limitation of the tetramer approach in the clinical diagnostic setting is that it is constrained by the number of HLA-peptide tetramer (multimer) combinations that are available for use with a particular antigen (*e.g.*, CMV, EBV). It also requires *a priori* knowledge of the patient's HLA genotype, and very often it does not incorporate a comprehensive assessment of the CD8 and CD4 cytotoxic T-cell response. Although some laboratories use only a quantitative approach to determine immune competence to pathogens, such as CMV with the tetramer assay, more comprehensive assays are available that also provide a functional assessment of these antigen-specific CD8 T cells (Fig. 93.7).

An alternative approach is to evaluate for cytotoxic function by assessing degranulation by evaluating for CD107a expression by the effector T cell (described in further detail in the NK cell function section) and/or evaluating IFNγ production by activated

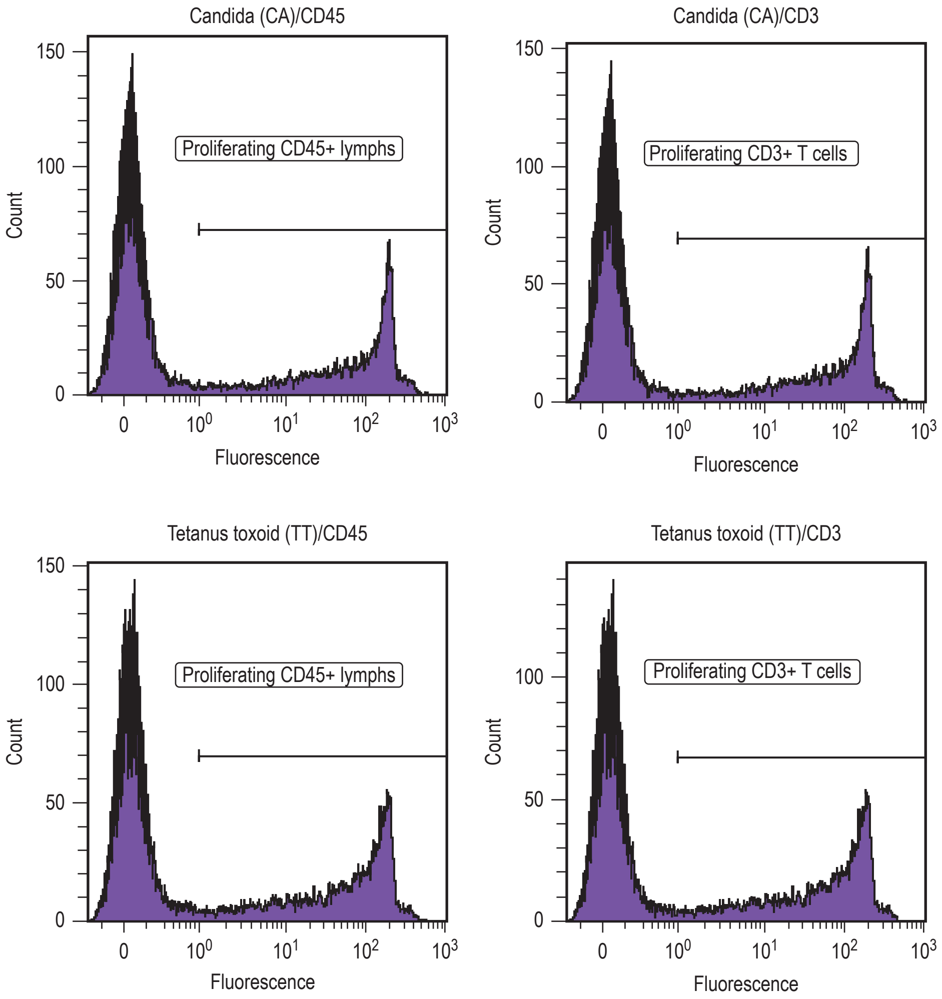

FIG 93.6 Assessment of Antigen-Specific T-Cell Proliferation. Antigens such as candida antigen (CA) and tetanus toxoid (TT) are frequently used to assess antigen-specific T-cell function. As with mitogens and anti-CD3 stimulation, proliferation is measured in total CD45$^+$ lymphocytes and CD3$^+$ T cells. An example in a healthy donor is shown.

cytotoxic CD8 T cells. As a positive control, CD8 T cells are polyclonally stimulated with PMA and ionomycin, and the same markers (CD107a expression and IFN-γ production) are measured. Approximately 10–60% of CD8 T cells in healthy adults are activated to express CD107a and to secrete IFN-γ under these conditions. An approach that avoids the use of tetramers involves the stimulation of patient-specific PBMC with overlapping peptide pools of the specific antigen and, subsequently, the evaluation of the CD8 and CD4 T cells that proliferate in response to antigenic stimulation. These T cells can also be assessed for cytotoxic potential by measuring intracellular perforin and granzyme expression as well as degranulation (CD107a expression) after stimulation.[8]

A CMV-specific assay has been developed that measures IFN-γ production in response to CD8 T-cell stimulation with a pool of MHC class I–restricted CMV peptides, the QuantiFERON-CMV (Cellestis Ltd., Melbourne, Australia).[14] This commercial assay is simpler to perform than the tetramer-based approach for quantification and functional analysis of antigen-specific CD8 T cells. It has been applied in the context of risk prediction for CMV in organ transplant and allogeneic hematopoietic cell transplant (HCT) patients. However, this assay has theoretical limitations in that assessing the production of a single cytokine is unlikely to represent the breadth of the immune response to a complex specific antigen such as CMV.

NK CELL ACTIVATION AND FUNCTION

NK cells are innate immune lymphocytes that provide the cellular basis for innate responses to specific viruses as well as to tumor cells[15,16] (Chapter 3). Unlike T and B cells of the adaptive immune system, NK cells do not have antigen-specific recognition and killing of target cells. NK cells participate directly in effector functions via cytotoxicity and production of cytokines (*e.g.*, IFN-γ) upon activation. Proinflammatory cytokines such as IL-12, IL-15, and IL-18 trigger NK cell proliferation as well as cytotoxicity and production of IFN-γ.[17] The negative regulation of NK cells is controlled by receptors that recognize MHC class I molecules preventing NK cell–mediated cytotoxicity. In contrast, virally infected or tumor cells typically downregulate MHC class I, making them appropriate targets of NK cell–mediated cytotoxicity in the presence of relevant ligands expressed by the target cell. NK cells, like cytotoxic T cells,[18] contain granules with cytotoxic proteins including perforin and granzymes, which are serine proteases that recognize different substrates.

NK CELL CYTOTOXICITY

The majority of NK cells can be identified by a lack of CD3 on the cell surface in conjunction with the expression of CD56 (NCAM [neural cell adhesion molecule]) and CD16 (FcγRIII). NK cells can be subdivided into two major subsets based on their relative expression of CD56 and CD16: CD16$^{+++(\text{bright})}$ CD56$^{+/-(\text{dim})}$ NK cells, referred to as cytotoxic NK cells, and CD56$^{+++(\text{bright})}$ CD16 or CD16$^{+/-}$ NK cells, known as regulatory or cytokine-producing NK cells (Fig. 93.8). The majority (~90%) of circulating human NK cells belong to the cytotoxic category, while a minority (10%) represent cytokine-producing NK cells. Cytotoxicity can be subdivided into natural or spontaneous cytotoxicity directed largely toward virally infected cells or tumor cells, in the absence

FIG 93.7A, B Quantitative of Antigen-Specific CD8 T Cells and Functional Evaluation Using Major Histocompatibility Complex (MHC) Class I Tetramers. The tetramer (multimer) technology has been useful for accurate quantitation of antigen-specific CD8 (or CD4 T cells, if MHC class II tetramers are used). The top panels show identification of CD3$^+$ T cells from total lymphocytes and subsequent segregation into CD3$^+$CD8$^+$ T cells. In this assay, cytomegalovirus (CMV)-specific CD8$^+$ T cells are quantitated using five MHC class I tetramers (human leukocyte antigen [HLA] A1, A2, B7, B8, and B35), each recognizing a unique CMV peptide from three major CMV antigenic proteins (pp50, pp65, and IE-1) as listed in the box. Based on the HLA class I haplotype of the individual, one or more tetramers are used for stimulation. The bottom panels show an example of a patient with HLA A2-specific CMV-CD8$^+$ T cells and another patient with HLA B8-specific CMV-CD8$^+$ T cells. These CMV-specific CD8$^+$ T cells can be assessed for functional capacity by gating on the tetramer-positive CD8$^+$ T cells and then measuring degranulation (CD107a expression) and inteferon (IFN)-γ production after *in vitro* stimulation with the specific CMV peptide (lower panel). The data are shown for CD107a expression and IFN-γ production in unstimulated CMV-CD8$^+$ T cells and peptide-stimulated CMV-CD8$^+$ T cells.

of prior stimulation or immunization, and antibody-dependent cellular cytotoxicity directed against antibody-coated target cells. NK cells go through a process of education or "licensing" whereby NK cells that express inhibitory receptors to self-MHC class I molecules are called licensed, which means they are more functionally responsive to stimulation, whereas unlicensed NK cells lack receptors for self-MHC class I and are hyporesponsive (Fig. 93.9).

NK cell function is measured in the clinical laboratory by assessment of spontaneous (natural) NK cell cytotoxicity using an MHC class I–deficient myelogenous leukemia cell line, K562. Traditional methods for measuring NK cell cytotoxicity are similar to those used for assessing cytotoxic T cell (CTL) function based on varying effector:target ratios in a 4- to 16-hr ^{51}Cr-release assay compared with the no-lysis and 100% lysis conditions as described for the T-cell cytotoxicity assay. However, there is interest in the use of flow cytometry to measure spontaneous or IL-2–activated (lymphokine-activated killer [LAK]) NK cell cytotoxicity in the clinical laboratory to avoid radioactivity. One flow cytometric assay employed in the clinical laboratory involves the use of fluorescently labeled (Cell Tracker® dyes) target cells (K562) incubated with effector cells (donor or patient PBMC) in the absence (spontaneous) or presence of IL-2 (LAK). Following coincubation, the lysis of target cells is measured by using 7-AAD (7-amino-actinomycin-D) (Fig. 93.10). IL-2 enhances cytotoxic function with increased lytic potential against a broad range of target cells. IL-2 has also been shown to induce IFN-γ secretion by NK cells with upregulation of activation markers, such as CD25 and CD69.[19] Treg cells control NK cell activation and cytotoxic function by limiting access to IL-2.[20] Other methods for measuring NK cell cytotoxic function that are primarily used in the research setting include the use of image cytometry,[21] microchip screening,[22] and flow-based assays using other dyes, such as calcein AM.[23]

The direct measurement of NK cell cytotoxic function is useful in a variety of clinical contexts, especially in patients with inherited immune defects affecting NK cells and function, including but not limited to recurrent/persistent herpesvirus infections and familial/primary hemophagocytic lymphohistiocytosis (FLH/HLH). There are other parameters that are widely used as surrogates of cytotoxicity, including flow cytometric measurement of granule exocytosis/degranulation. The membrane of cytotoxic granules in both NK cells and CD8 T cells is composed of several proteins, including CD107a (lysosomal-associated membrane protein 1 [LAMP-1]). On stimulation of NK cells and CD8 cytotoxic T cells, CD107a is upregulated and expressed on the cell surface (Fig. 93.11) concomitantly with cytokine secretion and target cell lysis, and therefore has been frequently used to

FIG 93.8 **NK Cell Subsets in Blood.** Natural killer (NK) cells are present as two major subsets in blood: cytotoxic NK cells (CD16^{++}CD56$^{+/-}$) and cytokine-producing NK cells (CD56^{++}). The former accounts for 90% of NK cells in circulation and the latter, 10%. The cytotoxic NK cells are very efficient in mediating target cell killing via spontaneous (natural), lymphokine-activated (LAK), or antibody-dependent cytotoxicity mechanisms. FIG 93.9 **NK Cell Recognition of Target for Cytotoxic Function.** Natural killer (NK) cells have inhibitory receptors for self-major histocompatibility complex (MHC) class I. Therefore NK cells do not kill target cells expressing MHC class I (upper panel). However, when MHC class I expression is downregulated (viral infections, tumors), the target cell is primed for NK cell cytotoxicity, which is mediated by granule exocytosis and release of cytotoxic proteins, including perforin and granzymes (lower panel). (Adapted from figure in French AR and Yokoyama WM. *Arthritis Res Ther* 2004;6:8–14.)

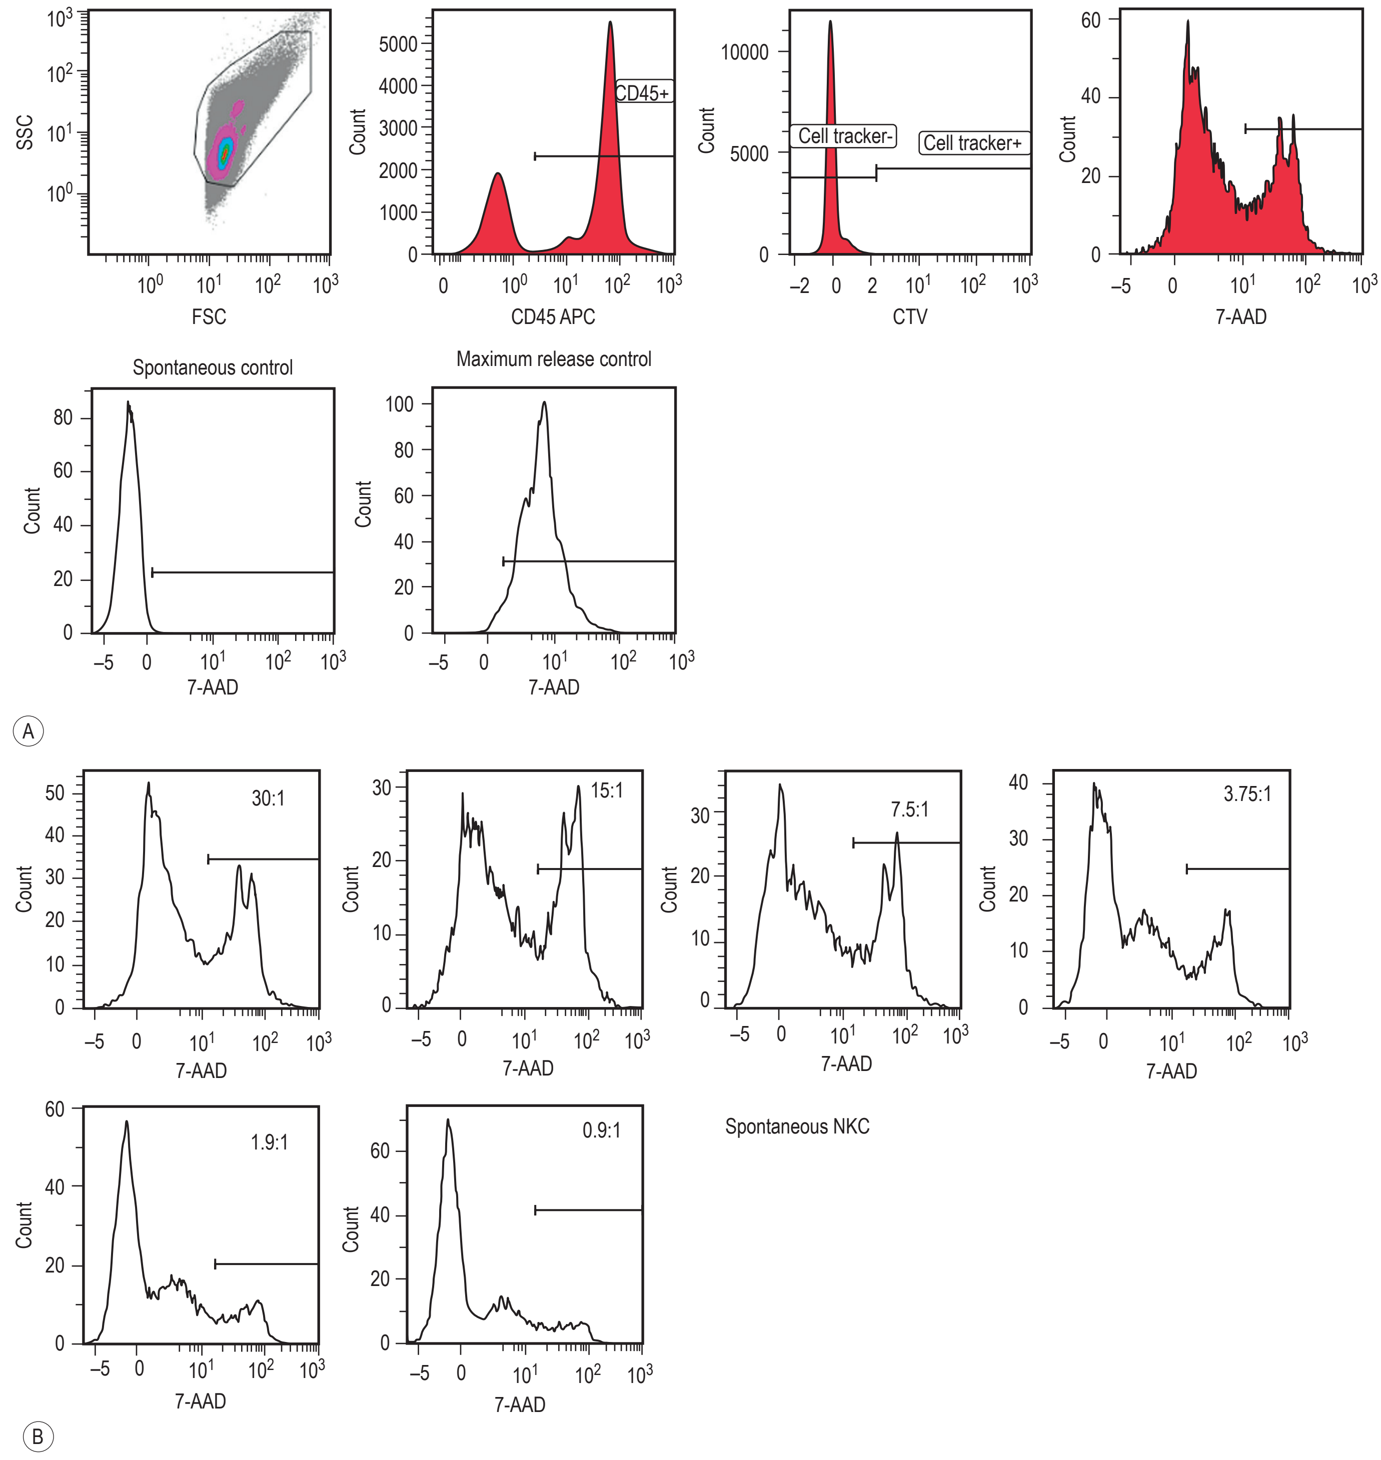

FIG 93.10A, B Flow Cytometric Assessment of Natural Killer (NK) Cell Cytotoxic Function. The "gold standard" for measuring natural killer cell cytotoxicity (NKC) uses a radioactive label for target cells. In the flow-based assay, target cells (K562, a major histocompatibility complex [MHC] class I–negative erythroleukemia cell line derived from a patient with CML, chronic myelogenous leukemia in blast crisis) are labeled with a fluorescent marker, Cell Tracker® (CTV). In the top panel, the gating strategy for analysis is shown. Peripheral blood mononuclear cells (PBMC) from healthy controls or patients are cocultured with labeled target cells, and the two cell populations are identified by forward scatter (FSC) and side scatter (SSC) parameters. Afterward, $CD45^+$ lymphocytes are identified because NK cells (effector cells) are within the lymphocyte subset. CTV^+ and CTV^- cells are separated; CTV^+ cells that are also 7-amino-actinomycin-D $(7\text{-AAD})^+$ are identified as killed target cells, and their frequency is estimated. A negative control for spontaneous cytotoxicity is achieved by incubation of labeled target cells without effector cells added (called spontaneous control). A positive control for maximal cytotoxicity is achieved by incubating labeled target cells for the same duration but using a permeabilization/fixation method to obtain maximal cell death and fluorescent-positive cells (called maximum release control). The middle panel depicts spontaneous NK cell cytotoxicity with different concentrations of effector cells (PBMC; E) to a single concentration of target cells (T) starting at 30:1. The data are expressed as delta (Δ)% cytotoxicity after the spontaneous control signal is subtracted from the E:T signal for each concentration (shown in the table).

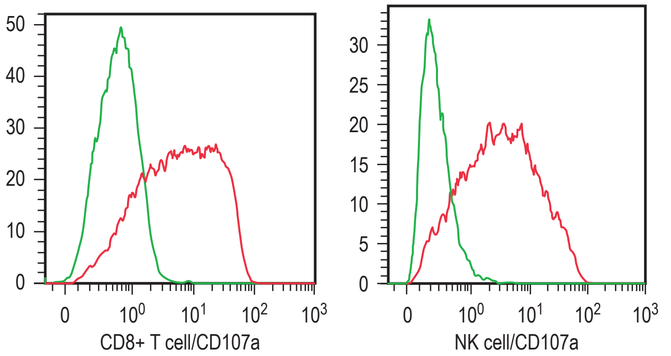

FIG 93.11 Cellular Degranulation Measurement. Cytotoxic lymphocytes undergo degranulation upon stimulation before mediating cytotoxic function. As a result of the degranulation process, CD107a, expressed intracellularly, is now expressed on the cell surface and can be assessed by flow cytometry. Degranulation can be determined in the CD8$^+$ T cells (left panel) and natural killer (NK) cells (right panel). In this analysis, peripheral blood mononuclear cells (PBMCs) were stimulated with phorbol myristate acetate (PMA) (10 ng/mL) and ionomycin (1 µg/mL) for 3 hours. Following stimulation, cells were stained for CD107a in CD8$^+$ T cells (left panel) and in NK cells (right panel). NK cells can also be stimulated with K562 cells as an alternative to mitogen stimulation. The degranulation assay is frequently used as a surrogate for, or as an adjunct to, measurement of cellular cytotoxicity.

extrapolate the magnitude of cytotoxic activity.[24,25] Degranulation (CD107a expression) assays have gained traction in the assessment of FHL.[26] The exception is in patients with mutations in the gene encoding perforin (*PRF1;* FHL type 2) where degranulation (CD107a expression) of cytotoxic cells is normal while cytotoxicity is abnormal. Therefore while degranulation assays may provide relevant information, they cannot substitute for direct measurement of cytotoxicity in all settings (Fig. 93.10B).

NK cells also mediate killing of target cells, via recognition of surface-bound immunoglobulin through the Fcγ receptors (Ig-Fc receptors, specifically CD16 or FcγRIIIa), through a mechanism called antibody-dependent cellular cytotoxicity (ADCC). ADCC has also traditionally used the ^{51}Cr method discussed above, although currently flow cytometry has largely replaced radioactive methods. ADCC assays are particularly relevant in the assessment of antitumor responses, especially of new biological immunomodulatory agents, as well as of the function of alloantibodies in allograft rejection. Recently a method for assessing ADCC by flow cytometry using cryopreserved PBMC has been described,[27] although most clinical laboratories use fresh samples in these functional assays.

EVALUATION OF REGULATORY T-CELL (TREG) FUNCTION

Regulatory T cells (FOXP3$^+$Treg) have been well described over the past several years as a distinct subset of T cells that are both developmentally and functionally unique and essential to maintaining immune homeostasis and self-tolerance.[28,29] The major subpopulations of Treg cells include natural Treg (nTreg) cells that are produced in the thymus and induced Treg (iTreg) cells that are generated in the periphery from conventional FOXP3$^-$CD4$^+$ T cells.[30] The dysfunction of Treg cells results in severe autoimmunity, with IPEX serving as the classic prototype[3,31] (Chapter 35). Besides their role in controlling development of autoimmunity, lack of Treg cells or abnormal Treg function has been implicated in the etiopathogenesis of graft-versus-host disease (GVHD)[32] and allograft rejection, while its presence and normal function have been shown to promote allograft tolerance in solid-organ transplantation.[33,34]

KEY CONCEPTS

Regulatory T Cells and B Cells

- Regulatory T cells (Tregs) and B cells (Bregs) are distinct subsets of cells with immune regulatory potential and importance in maintaining immune homeostasis and self-tolerance, preventing autoimmunity, and limiting inflammatory damage.
- FOXP3 transcription factor is a marker for natural regulatory T cells; while there are no specific cellular markers that define Breg, production of interleukin (IL)-10 is considered a hallmark.
- Both Treg and Breg have been shown to play important roles in autoimmunity, in graft-versus-host disease (GVHD), and in mediating transplant tolerance.
- Treg function is measured *in vitro* through different types of suppression assays, while Breg are characterized by their ability to produce IL-10 when stimulated via Toll-like receptor (TLR9)/B-cell receptor (BCR) or CD40L crosslinking.
- Natural, thymic-derived Treg are CD4$^+$25$^+$FOXP3$^+$ while Breg are CD19$^+$CD24^{hi}CD38^{hi}IL-10$^+$.
- Treg can also be induced in the periphery from conventional T cells through cytokine signals (iTreg).

Treg cell function is measured *in vitro* with Treg suppression assays, which utilize sorted CD4$^+$CD25$^+$ Treg cells in a coculture system with conventional effector T cells to assess suppression of proliferation.[35] However, there are limitations to this approach, including the issue of whether the Treg suppression assays *in vitro* reflect the biological process *in vivo.* In addition, antigen-specific Treg suppression cannot be adequately assessed due to the technical difficulties in obtaining sufficient numbers of antigen-specific cells, so the use of a polyclonal activation model with bulk PBMC represents the standard to study Treg suppression. Rapid tests for Treg cell function have been described using short-term (7–20 hr) flow-based assays to measure suppression of T-cell activation marker expression (CD40L and CD69). These assays utilize effector T cells (CD4$^+$25$^-$) activated with anti-CD3/anti-CD28 beads with and without the addition of freshly isolated Treg cells or *ex vivo* expanded Treg cells.[36,37] When implementing Treg suppression assays in the clinical diagnostic laboratory, a number of technical considerations can confound the interpretation of results, and these are well described by McMurchy *et al.*[38] Also, it remains unclear whether standard *in vitro* Treg suppression assays can adequately account for the significant complexity of Treg subsets that may have different functional properties in various clinical contexts. Therefore the newer techniques of mass cytometry may be required to address the phenotypic diversity[39] and to eventually be harnessed either to evolving applications or other technology to analyze the functional complexity of these populations.

ASSESSMENT OF SIGNALING AND DNA REPAIR PATHWAYS IN LYMPHOCYTES VIA PHOSPHOFLOW CYTOMETRY

A key aspect of studying lymphocyte responses is to assess signaling in appropriate lymphocyte subsets and its alteration in pathological conditions. A versatile tool called phosphoflow is unique in its ability to allow the study of multiple intracellular signaling molecules in specific lymphocyte populations at a single-cell level.[40] Phosphoflow assays for the signal transducer and activator of transcription (STAT) molecules[41,42] (Fig. 93.12) have been well described and are discussed in Chapter 92. The use of phosphoflow assays to assess Bruton's tyrosine kinase (BTK) phosphorylation in X-linked agammaglobulinemia (XLA) with leaky (hypomorphic) defects as well as to assess radiosensitivity and the DNA repair pathway will be covered briefly.

Mutations in *BTK* impair B-cell maturation and function, and patients with XLA can have either no peripheral B cells (null mutations) or reduced B cells (hypomorphic/leaky mutations), depending on the specific genetic defect (Chapter 34). Two regulatory tyrosine residues in BTK undergo rapid phosphorylation upon B-cell receptor (BCR) cross-linking (Y551 within the SH1 domain and Y223 in the SH3 domain).[43] Y551 is transphosphorylated by Src family kinases whereas Y223 is autophosphorylated. Phospho-BTK accounts for a small fraction (<5%) of the total BTK pool in BCR-activated B cells. BTK molecules are singly or doubly tyrosine-phosphorylated, and Y551 phosphorylation increases BTK activity, whereas Y223 phosphorylation is likely more relevant for protein-protein interactions due to its presence in the SH3 domain. Since the phosphorylation events are sequential (Y551 before Y223), the dephosphorylation event is also successive in the same order. In the flow assay, Y223 phosphorylation is measured after an anti-IgM antibody is used

FIG 93.12 Analysis of Phosphoproteins in Cells by Flow Cytometry. Cells activated by specific stimuli can be assessed for activation and induction of specific signaling pathways by measuring phosphoproteins: A single stimulus or multiple stimuli can be used to phosphorylate different proteins, and intracellular staining can be performed with phospho-specific antibodies, which is subsequently analyzed by multicolor flow cytometry. See text for detailed explanation. (Figure modified from Figure 2 by Krutzik PO, et al. *Clin Immunol* 2004;110:206–21; published in previous edition of this book.)

KEY CONCEPTS

Assessment of DNA Repair Pathways by Phosphoflow

- DNA double-strand break (DSB) repair defects are relevant to VDJ recombination, isotype class switching, and lymphocyte maturation.
- Defects in this process can lead to immunodeficiency with susceptibility to infection and malignancy.
- Homologous recombination (HR), which is error-free, involves RAD50, RAD51, RAD52, and Mre11, while nonhomologous end-joining (NHEJ) is error-prone and utilizes Ku70/80, DNA-PKcs, Artemis, DNA Ligase IV, XRCC4, XLF/Cernunnos.
- ATM is a key regulator of cell-cycle checkpoints following irradiation-induced DSB and coordinates timing of phosphorylation of checkpoint proteins.
- Cell cycle analysis can help identify checkpoint defects and can be easily assessed by flow cytometry.
- Phosphorylation of H2AX (γH2AX) is a useful marker of DNA damage related to irradiation-induced DSB.
- However, several kinases phosphorylate H2AX, which can confound identification of specific defects; therefore assessing multiple proteins in the pathway allows identification of a broader group of DNA repair defects.
- Measurement of 53BP1 phosphorylation is a useful surrogate marker of the integrity of the chromatin ubiquitin ligase pathway.

to cross-link the BCR (for 3 minutes), because Y551 phosphorylation could not be detected in the time interval the assay was performed. In addition to PBMC, Ramos cell line (a B-cell line derived from a patient with Burkitt lymphoma) is used as a control for B cells, while pervanadate (complex of vanadate with hydrogen peroxide), an irreversible protein tyrosine-phosphatase inhibitor, is used in this assay as a positive control (Fig. 93.13). In the Ramos cell line, it is possible to visualize the Y551 phosphorylation (Fig. 93.13) with pervanadate treatment.

A number of genetic disorders, collectively classified as XCIND (x-ray [irradiation] sensitivity, cancer susceptibility, immunodeficiency, neurological involvement, and double-strand DNA breakage), cause impairment in cellular ability to repair DNA double-strand breaks (DSB). These defects have a significant impact on the ability of cells to grow, differentiate, and function normally; they include ataxia telangiectasia (AT) due to *ATM* gene mutations and radiosensitive severe combined immunodeficiencies (rs-SCID) due to mutations in the *DCLRE1C, LIG4, NHEJ1,* and *PRKDC* genes. These disorders make it very desirable to have an assay capable of rapidly assessing DNA repair in lymphocytes in response to radiation damage. A flow cytometry assay has been developed that is capable of measuring the function of several proteins in the DNA repair pathway after induction of DSBs via irradiation (Fig. 93.14A). The assay includes assessment of nonphosphorylated ATM protein and 53BP1[44,45] without irradiation to determine the amount of native protein present. Following low-dose irradiation, the function of ATM and ATR (ATM-Rad3–related kinase) pathways are assessed by analyzing the autophosphorylation of ATM at serine 1981. This step is required for ATM activation and is followed by phosphorylation of downstream targets SMC1, H2AX, 53BP1, and CHK1. H2AX is a histone that belongs to the H2A family and is a component of the histone octamer in nucleosomes. It is phosphorylated by both ATM and ATR and is the first step in the recruitment and localization of DNA repair proteins.[46] In patients with AT, there is a complete absence of phosphorylation of ATM, SMC1, and 53BP1 after irradiation-induced DSBs. Phosphorylation of H2AX appears normal, as it is also phosphorylated by ATR; however, the magnitude of phosphorylation is significantly decreased (Fig. 93.14B). The kinetics of phosphorylation indicates that maximal phosphorylation occurs 1 hr after induction of DSB and that there is dephosphorylation by 24 hr postirradiation (not shown). This flow-based assay enables a rapid assessment of radiation sensitivity as well as the ability to visualize the function of multiple proteins of the DNA repair pathway. It can also be used to characterize the DNA repair function of known and unknown genetic defects, and it can identify functional phenotypes in patients with atypical presentations that may be missed if only genetic information is used.

ASSESSMENT OF B-CELL FUNCTION

While T cells and NK cells form the foundation of the cellular immune response, B cells are the main driver of humoral immunity. B cells are multifaceted in their function; they produce antibodies via differentiation into plasma cells, they act as APCs for T cells, and they secrete potent immunomodulatory cytokines while downregulating immune responses via IL-10 production. B cells can proliferate in response to polyclonal mitogenic stimuli such as PWM (Fig. 93.15), albeit with a much weaker response than seen with T cells stimulated with PHA (Fig. 93.3). Clearly, the starting point for any evaluation of B-cell function involves measuring serum immunoglobulin levels followed by *in vivo* antibody responses to vaccination with both protein (*e.g.,* tetanus toxoid) and carbohydrate (*e.g.,* Pneumovax 23) antigens.[47]

A more recent area of focus in laboratory evaluation of B cells has been the regulatory function of B cells, specifically with regard to the subset classified as regulatory B (Breg) cells. B cells that secrete IL-10 have been described as Breg cells and are now recognized to be an important component of the host immune response that protects against autoimmunity and also limits inflammatory damage.[48,49] In humans, the phenotype of Breg cells has been described as $CD19^+CD27^-CD24^{hi}CD38^{hi}CD5^+CD1d^{hi}$. However, the ability to produce IL-10 appears to be the defining feature rather than any particular constellation of cell-surface markers.[50] Also, unlike Treg cells, no exclusive transcription factor equivalent to FOXP3 is expressed in Breg cells. In general, $IL\text{-}10^+$ Breg cells in blood and spleen appear to be enriched in the $CD19^+CD27^+CD24^{hi}$ memory B-cell subset. IL-10 exerts potent antiinflammatory effects and enhances survival, proliferation, differentiation, and isotype class-switching of B cells. Both naïve and memory human B cells have the ability to produce IL-10 in response to stimulation via TLR9 and the BCR, but only ~15% of B cells can produce IL-10 in response to stimulation. Stimulation through CD40L or IL-21 also promotes differentiation of IL-10–producing Breg cells. $CD19^+CD24^{hi}CD38^{hi}$ Breg cells play critical regulatory roles in autoimmune disease, chronic GvHD, and transplant tolerance.[51-53]

In the diagnostic laboratory, Breg cells can be assessed by isolating PBMC from blood and culturing with CpG-B (TLR9 stimulation) or CpG-B plus recombinant CD40L for 3 days *in vitro,* followed by the addition of PMA, ionomycin, and brefeldin A (BFA) for the last 5 hours of culture. Cells can then be harvested, washed, and stained with CD19 and IL-10 antibodies (the latter requires intracellular staining) and then analyzed with a flow cytometer. To assess the presence of Breg cells in blood without *in vitro* differentiation, blood or PBMC can be analyzed for $CD19^+CD24^{hi}CD38^{hi}$ B cells that are positive for intracellular

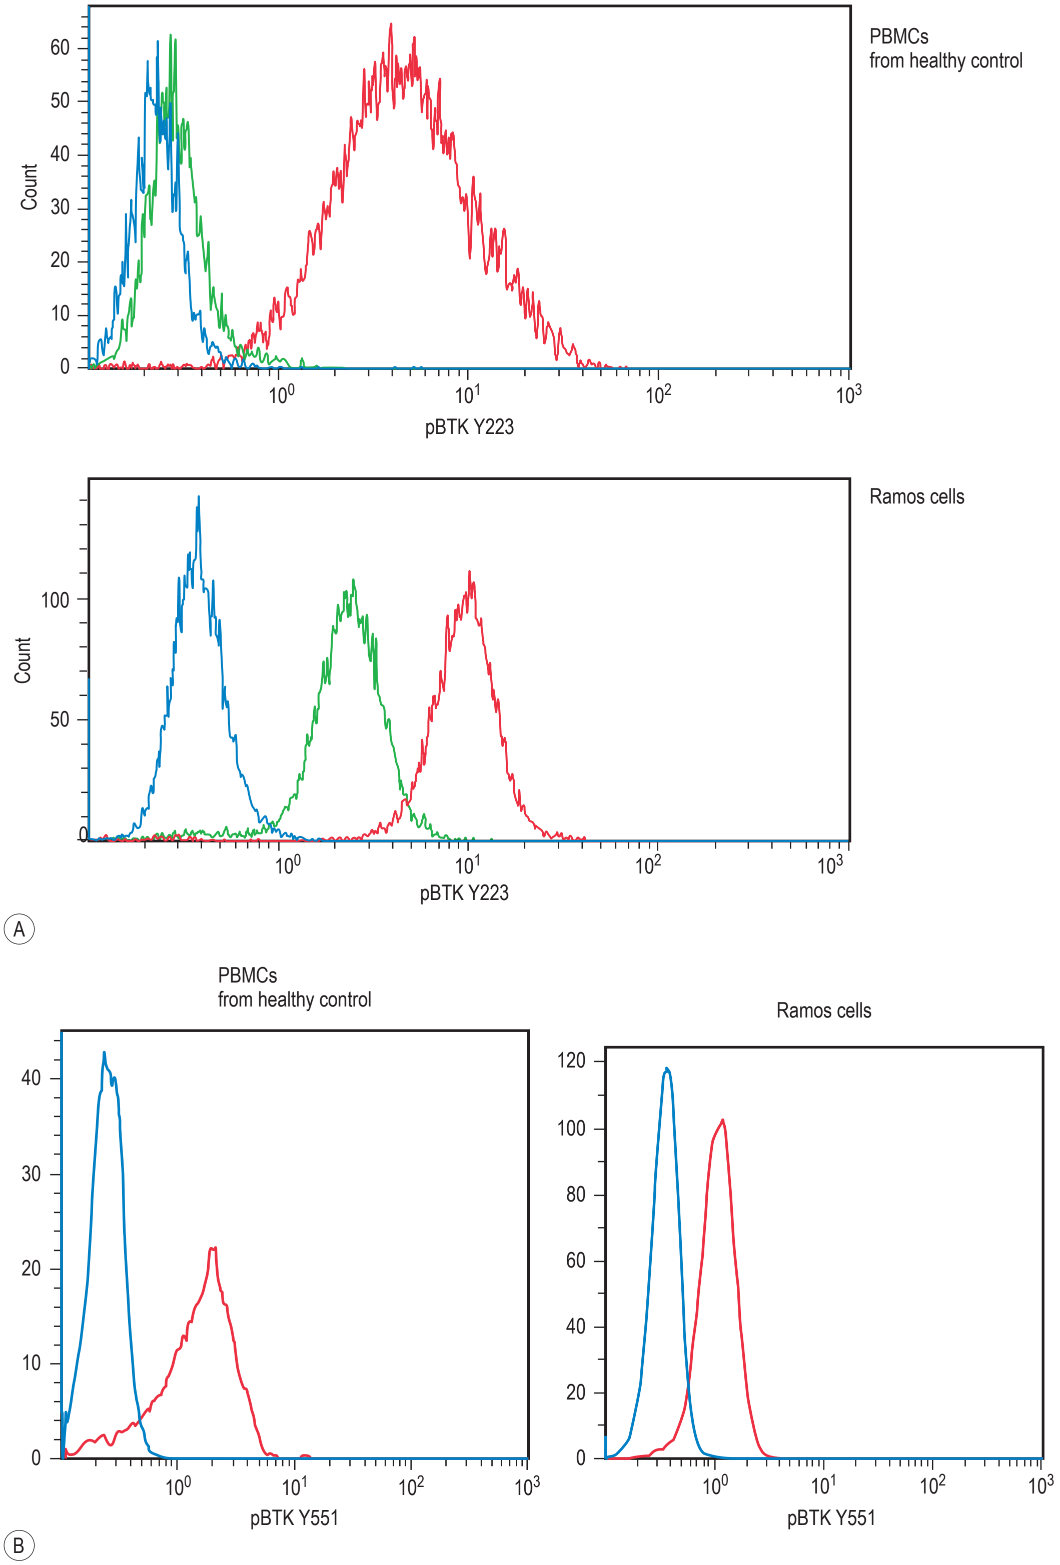

FIG 93.13A, B Analysis of BTK Phosphorylation in PBMC and Ramos B-Cell Line. Bruton's tyrosine kinase (BTK) phosphorylation can be assessed in B cells in X-linked agammaglobulinemia (XLA) patients with leaky defects who have some preserved B cells in blood. B cells are stimulated with either anti-immunoglobulin M (IgM) (B-cell receptor [BCR] cross-linking; green line) or pervanadate (positive control; red line). The example shown here is for BTK phosphorylation at the Y223 residue in peripheral blood mononuclear cells (PBMCs) from a healthy donor (top panel) and a B-cell line, Ramos cells. The blue line represents the unstimulated control. In the bottom panel, BTK phosphorylation of the Y551 residue is shown for PBMCs from a healthy donor (left) and Ramos cells (right). The phosphorylation of the Y551 residue cannot be visualized for anti-IgM stimulation, and therefore data are shown only for the positive control, pervanadate.

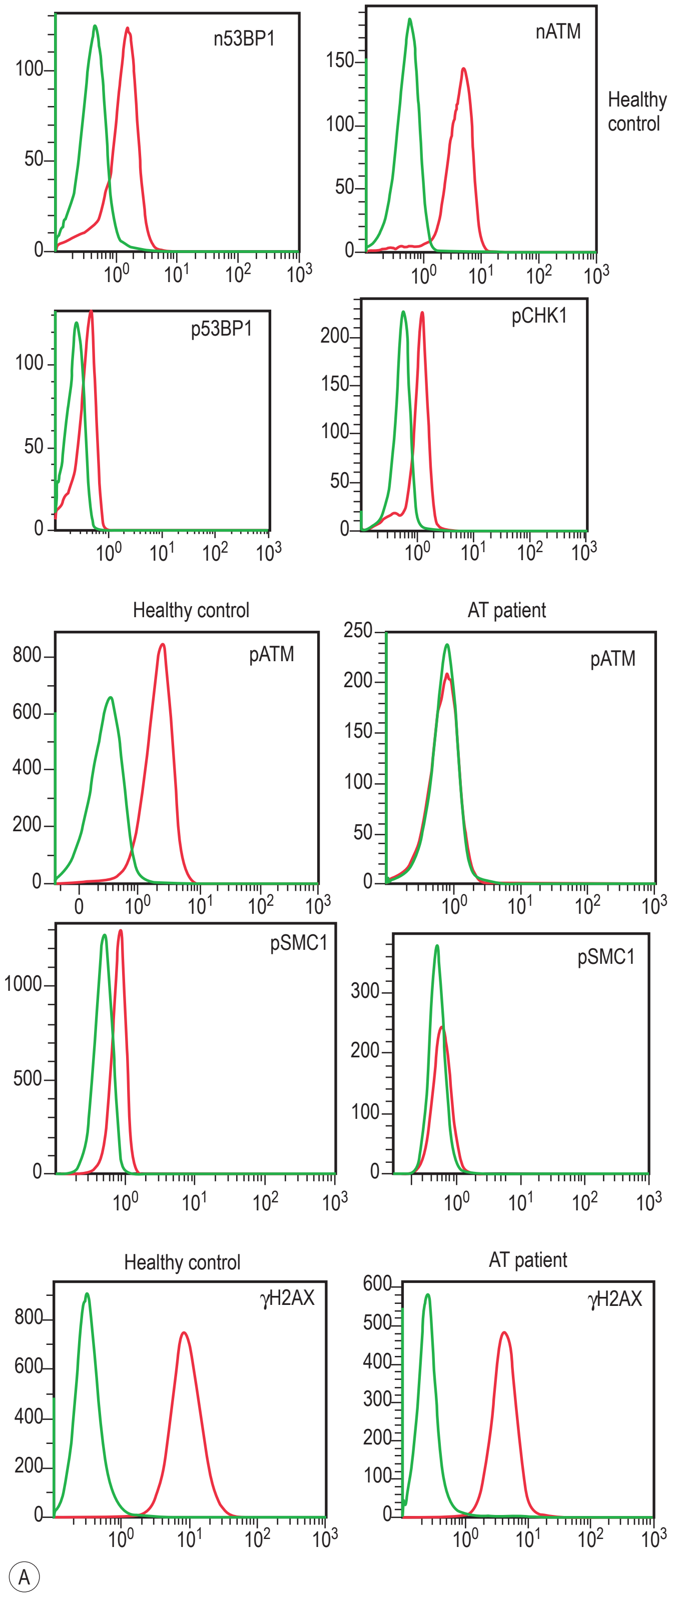

FIG 93.14A **Assessment of Radiosensitivity in Lymphocytes by Flow Cytometry.** DNA repair pathway defects can be rapidly and sensitively analyzed by flow cytometry. The top panel shows expression of native (nonphosphorylated) 53BP1 and ATM proteins and phosphorylated (p) 53BP1 and CHK1 proteins in total lymphocytes. The lower panels demonstrates normal ATM autophosphorylation in T cells of a healthy donor and absent (abnormal) phosphorylation of ATM in T cells of a patient with ataxia telangiectasia (AT) on exposure to low-dose (2 Gy) radiation. The green line represents the unirradiated sample, and the red line represents the data postirradiation. AT patients also show an inability of ATM to phosphorylate downstream targets, such as SMC1 in T cells. This is also true for other lymphocyte subsets (B cells and natural killer [NK] cells). Histone H2AX is phosphorylated (γH2AX) as a result of DNA double-strand breaks (DSBs) from exposure to radiation. No defect is apparent in γH2AX in AT when assessing the frequency of cells that express γH2AX.

	MFI (γH2AX)
Donor	10.13
Patient-AT	4.72

FIG 93.14B **The Relevance of Assessing Mean Fluorescence Intensity for Flow-Based Radiation Sensitivity Analyses.** Mean fluorescence intensity (MFI) can provide additional valuable information on DNA repair defects and should be used along with frequency analysis, as demonstrated in Fig. 93.14A. In ataxia telangiectasia (AT) patients, although the proportion of γH2AX appears normal, it is significantly decreased (by >50% in AT (purple bar) compared with healthy controls (blue bar).

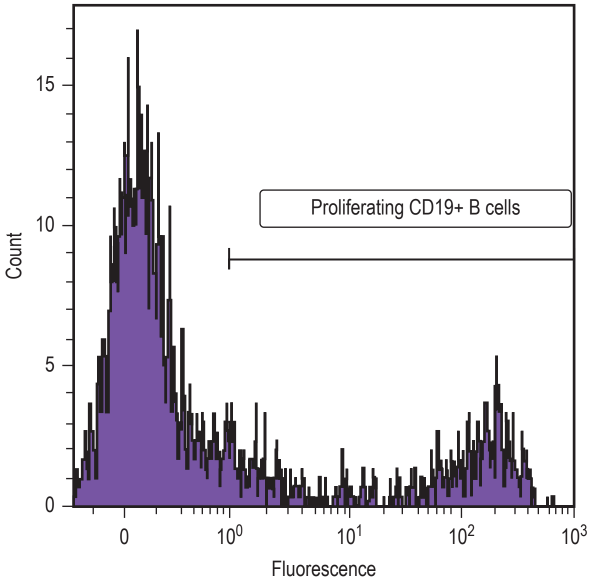

FIG 93.15 Assessment of B-Cell Function by Measuring Proliferation to Mitogen. B cells can proliferate on stimulation with certain mitogens, similar to T cells. B cells do not respond well to phytohemagglutinin (PHA) but can proliferate *in vitro* on stimulation with pokeweed mitogen (PWM), although it is a relatively weak B-cell stimulant. B-cell proliferation can be assessed by flow-based proliferation in CD19⁺ B cells.

IL-10 using a similar flow cytometry protocol, but the levels of these cells can be highly variable, and accuracy of detection and quantitation is likely to be dependent on the analytical method and clinical context.*

SUMMARY

ON THE HORIZON

- The advent of newer assays, including flow cytometry based as described herein, are likely to replace traditional and often less sensitive radioactive or other cumbersome methods for assessing lymphocyte function.
- Microchip and advanced mass cytometry techniques, along with imaging cytometry, may offer newer, multiplex approaches to the assessment of lymphocyte subsets, individually and in cellular interactions.
- Functional and phenotypic data need to be ideally correlated with relevant genomic, transcriptomic, proteomic, metabolomic, epigenomic, and microbiome analyses for effective characterization of the complex interactions that govern the immune response in the normal and dysregulated state.
- This will necessitate further refinements of "big data" analysis, which can include, but is not limited to, experimental studies in addition to computational modeling. Examples include antigen-specific characterization of individual B-cell and T-cell receptors in an individual as an extension of current "deep-sequencing" repertoire analysis or transcriptomic analysis during immune quiescence or activation on a multidimensional scale.

In conclusion, lymphocyte responses in humans can be assessed using a variety of analytical tools as described in this chapter and applied to many clinical contexts, including but not limited to primary immunodeficiencies, autoimmunity, transplantation, and immune dysregulation disorders. Most of these measurements use cells from blood and not from other lymphoid tissues due to accessibility and ease of generating control reference ranges. This chapter is not an exhaustive treatise on all aspects of lymphocyte function and the immune response; nor does it cover all areas of normal and abnormal pathology in this context. Rather, it is meant to take the reader on a tour of the immune landscape and to provide salient highlights of the diversity and relevance of lymphocyte function.

MULTIPLE-CHOICE QUESTIONS

1. CD40L is an early activation marker present primarily on which lymphocyte subset?
   A. B cells
   B. Natural killer (NK) cells
   C. Regulatory T cells
   D. CD4 T cells

2. Natural killer (NK) cells recognize target cells in a cytotoxicity assay by which of the following mechanisms?
   A. Absence of CD16
   B. Absence of NKp46
   C. Absence of major histocompatability complex (MHC) class I
   D. Absence of MHC class II

3. The histone H2AX is phosphorylated (γH2AX) by which of the following kinases, in addition to ATM?
   A. BTK
   B. LCK
   C. ATR
   D. ITK

4. Which of the following cytokines is a hallmark of B cells that possess regulatory function (Breg)?
   A. Interleukin-6 (IL-6)
   B. IL-10
   C. IL-2
   D. IL-21

Assessment of Neutrophil Function

Debra Long Priel, Douglas B. Kuhns

Neutrophils, also known as polymorphonuclear neutrophils (PMNs; because of their multilobed nucleus) or granulocytes (because of the numerous granules found in the cytoplasm), are major contributors to innate host defense against invading microorganisms, particularly bacteria and fungi. Neutrophils are bone marrow–derived, terminally differentiated cells that are incapable of further cellular division but may be also be derived from progenitor populations in the spleen.[1] Early studies indicated that neutrophils have a short life span in the circulation ($t_{1/2}$= 6–8 hours) and then survive an additional 1–2 days in the surrounding tissue;[2] more recent data suggest that neutrophils may survive 10 times longer in circulation, up to 5.4 days.[3]

Neutrophils, with a diameter of 10–15 μm and a volume of 346 μm^3, have a unique morphology. The nucleus of the mature neutrophil is segmented into 3–5 lobes with chromosomes randomly distributed among the lobes. Neutrophils also have an extensive array of storage granules prepackaged with specific proteins defined by the differentiation stage during maturation.[4] Granules are classified into four distinct populations: azurophilic, specific, gelatinase, and secretory granules. Azurophilic granules contain myeloperoxidase, lysozyme, antimicrobial peptides, defensins, proteases, and the lysosomal acid hydrolases. The specific granules contain lactoferrin, lysozyme, and vitamin B_{12}–binding protein and also serve as storage pools for CD11b/CD18 and cytochrome b_{558} of the superoxide anion radical ($O_2^{\bullet-}$)–generating enzyme, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, or NOX2. The gelatinase granules are a subset of the specific granules that have a high content of gelatinase. The secretory granules are highly mobilizable intracellular vesicles that contain alkaline phosphatase and other surface antigens.

The primary function of neutrophils is the ingestion (phagocytosis) and subsequent killing of microorganisms. This process requires the assembly of NOX2, a multiphagocyte oxidase (phox) component enzyme complex consisting of at least three cytosolic components—p47^{phox}, p67^{phox}[5], and p40^{phox}[6] —and two membrane components—p22^{phox} and gp91^{phox}—that constitute cytochrome b_{558}.[7,8] This enzyme reduces molecular O_2 to $O_2^{\bullet-}$ using NADPH generated by the oxidation of glucose through the pentose phosphate pathway; $O_2^{\bullet-}$ either spontaneously or enzymatically converts to hydrogen peroxide (H_2O_2). In the presence of a metal, such as iron (Fe^{2+}), H_2O_2 and $O_2^{\bullet-}$ can react to form the highly reactive hydroxyl radical, $OH^{\bullet}$. Alternatively, the azurophilic granule constituent, myeloperoxidase, catalyzes the formation of hypochlorous acid from H_2O_2 and chloride (Cl^-). The combined activities of these reactive O_2 species (ROS), antimicrobial peptides, and lysosomal hydrolases result in the ultimate destruction of the ingested microorganism. Excess production of ROS and release of lysosomal hydrolases into the extracellular milieu can lead to tissue damage and inflammation.

Neutrophils can also contribute extracellular microbicidal activity through the formation of neutrophil extracellular traps (NETs), a matrix of DNA and granular enzymes that is purported to entrap bacteria and promote their killing.[9] During NET formation, the nucleus loses its lobular shape, the nuclear membrane disintegrates into a chain of vesicles surrounding the DNA, and granular integrity is lost. The nuclear material fills most of the cell, mixing with the granular contents. The cells round up and DNA is forcibly extruded from the cell, conveying with it granular enzymes trapped within the DNA matrix. Mitochondria in neutrophils are few in number and exhibit relatively little oxidative phosphorylation but may play an important role in NET formation. Activation of neutrophils by immune complexes results in marked depolarization of the mitochondria, increased mitochondrial ROS production, and redistribution of the mitochondria to the periphery of the neutrophil. A low-density subset of neutrophils may be more prone to NET formation.[10]

Neutrophils display a diverse array of cellular functions. Abnormalities in these functions can severely compromise host defense, leading to recurrent bacterial and fungal infections (Chapter 22). To localize specific deficiencies of neutrophil function, assays have been developed that mimic these functions both *in vivo* and *in vitro.* Often, a preliminary screening of several neutrophil functions is performed to localize deficits and then more vigorous testing of specific function is performed. Assays to assess neutrophil function should address several limitations—the number of cells required for the assay, the type of cell preparation needed (isolated neutrophils versus whole blood), the overall incubation time for the assay, the complexity of the assay, and the rapidity of data collection. These issues become more critical if multiple functional assays are planned concurrently. Since neutrophils cannot be stored or frozen and maintain viability, neutrophils from a normal subject are generally assayed in parallel to validate the results, doubling the number of assays to be performed. Additionally, isolation of neutrophils can take 1–2 hours, limiting the time available for functional assays. Fluorescent probes have increased the sensitivity of many of the assays and eliminated the need for radioactive probes. The use of multiwell microplates and microplate readers has reduced the number of cells required and has facilitated the collection of data. Experience in the handling of neutrophils and the time constraints of assays can limit the availability of this testing to laboratories that specialize in assessment of neutrophil function.

KEY CONCEPT

Criteria to Assess Neutrophil Function

Because of (1) the time required to isolate neutrophils and (2) the shortened life span of neutrophils after isolation, assays of neutrophil function should have minimal complexity and enable rapid data collection.

KEY CONCEPT

Estimated Yield from Whole Blood

In general, 1–2 × 10^6 neutrophils can be isolated per milliliter of whole blood from a normal subject with a normal white blood cell count.

ISOLATION OF NEUTROPHILS

Clinical Indications and Implications

Assays that avoid neutrophil isolation are preferred because of the artificial priming of neutrophils during isolation.[11] However, most assays require isolated neutrophils to eliminate any possible contributions of other leukocytes and blood components. In general, blood should be drawn using either citrate or heparin as anticoagulant and maintained at 20–25°C in polypropylene containers. Most isolation protocols require 1–2 hours to obtain purified neutrophils.

Principles and Interpretation of Laboratory Assessment

Most neutrophil isolation protocols use differences in the cell density as the basis for the separation. The relative densities of blood cells are as follows: erythrocytes > neutrophils and eosinophils > monocytes, lymphocytes, and basophils > platelets. Ficoll-Paque is a solution of sodium diatrizoate (a dense, triiodinated compound) and Ficoll (a polysaccharide) with a density (1.077 g/cc) that falls between the density of neutrophils and that of the mononuclear cells. To isolate neutrophils,[12] whole blood is diluted with saline and underlaid with Ficoll-Paque solution. After centrifugation for 30 minutes at 500 g, the less-dense monocytes, lymphocytes, basophils, and platelets remain at the upper interface of the Ficoll-Paque solution, whereas the denser erythrocytes and neutrophils pass through the solution and pellet at the bottom. The mononuclear cells are carefully harvested and the remaining Ficoll-Paque solution aspirated. The erythrocyte/neutrophil pellet is resuspended with saline and mixed with 3% dextran. Dextran promotes the formation of rouleaux by the erythrocytes, causing them to sediment more rapidly than the neutrophils at 1 g. The neutrophil-enriched supernatant fluid is harvested from the bulk of the erythrocytes. Contaminating erythrocytes are removed by a brief (30-second) hypotonic lysis with 0.2% saline. The isotonicity is quickly restored with an equal volume of 1.6% saline. A second hypotonic lysis removes many of the red blood cell (RBC) ghosts. In general, 1–2 × 10^6 neutrophils can be isolated per milliliter of whole blood from a normal subject with a normal white blood cell (WBC) count. All procedures are performed at room temperature, and the isolated cells are maintained in a balanced salt solution without divalent cations. The most common cell contaminants of the neutrophil preparation are eosinophils. Further purification of a standard neutrophil preparation with anti-CD16 magnetic immunobeads results in a neutrophil preparation that is generally ≥99% neutrophils. A second neutrophil isolation protocol that uses a discontinuous gradient of plasma/Percoll has often been used to minimize exposure of neutrophils to trace contamination by bacterial lipopolysaccharide (LPS) and reduce neutrophil priming.[13]

Isolated neutrophils are routinely frozen in aliquots of 5 × 10^6 cells/vial. For Western blot studies, neutrophils (1 × 10^6 cells/mL of buffer) are pretreated for 20 minutes with the cell permeant, irreversible serine protease inhibitor, diisopropylfluorophosphate (DFP, 1–5 mM). DFP is a volatile, potent neurotoxin that can irreversibly bind to and inactivate acetylcholinesterase and should be used with extreme caution. The cell suspension is then spun and the supernatant fluid removed from the cell pellet before freezing. Waste solutions and disposable laboratory items should be flushed with sodium hydroxide to inactivate any residual DFP. These frozen neutrophil pellets, though not viable, can also be a source of DNA for genetic analyses.

HISTOCHEMICAL ANALYSIS OF NEUTROPHILS

Clinical Indications and Implications

Because of their unique morphology, microscope examination of neutrophil preparations with a differential stain, such as Wright stain, or a histochemical stain, such as Kaplow stain, for myeloperoxidase[14] remains an essential element of neutrophil study and can provide valuable insight into some genetic immunodeficiencies.

Principle and Interpretation of Laboratory Assessment

In Wright's stain, the nucleus of a segmented neutrophil is normally multilobed (usually 2–5 lobes), and each lobe is connected by a narrow filament (Fig. 94.1A). The nuclear chromatin is coarsely clumped with purple staining. Nucleoli are generally not present. In a band neutrophil, the nucleus is horseshoe shaped, with no indication of constriction into lobes. The pink-violet staining of the cytosol is associated with numerous, evenly distributed, specific granules; occasionally a dark-staining primary granule may be present. Kaplow stain[14] identifies the myeloperoxidase-containing primary granules as dark blue granules uniformly distributed throughout the cytosol (Fig. 94.1B). Neutrophils (and platelets) from patients with Chédiak-Higashi syndrome have giant primary granules that are generally considered pathognomonic for the disease (see Fig. 94.1C).[15] Myeloperoxidase staining of Chédiak-Higashi neutrophils is very distinctive, with staining localized to the discrete giant primary granules (see Fig. 94.1D). Neutrophils from a patient with specific granule deficiency exhibit primarily bilobed nuclei (pseudo–Pelger-Huët anomaly) with a paucity of specific granule staining in the cytosol (see Fig. 94.1E).[16] Staining of the myeloperoxidase granules of neutrophils from a patient with specific granule deficiency appears normal, since the defect is primarily associated with the specific granules (see Fig. 94.1F). Neutrophils from a patient with myeloperoxidase deficiency fail to stain for myeloperoxidase in the neutrophils. However, the peroxidase in the eosinophilic granules continues to stain positive (see Fig. 94.1G).[17]

ANALYSIS OF GRANULE CONSTITUENTS

Clinical Indications and Implications

The granules of the neutrophils can be distinguished by their specific contents. Deficiency of only one granule constituent can be associated with a specific genetic defect, such as myeloperoxidase deficiency; alternatively, deficiency of multiple constituents

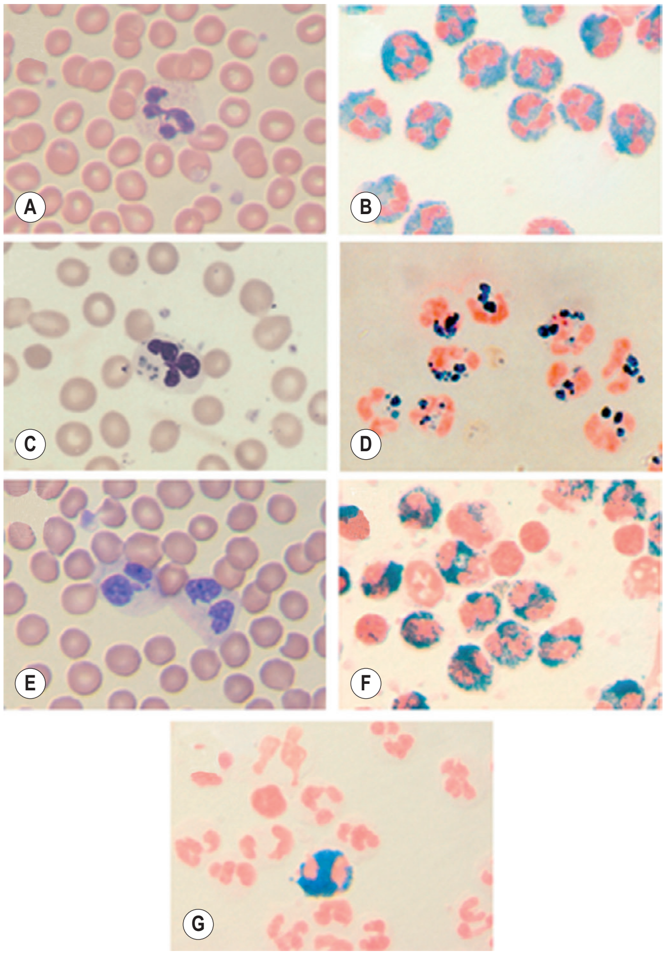

FIG 94.1 **Neutrophils Stained With Wright Stain and Kaplow Stain.** (A, C, and E) Blood smears stained with Wright stain. (B, D, F, and G) Neutrophil preparations stained with Kaplow stain. (A, B) Neutrophils from a normal subject. (C, D) Neutrophils from a patient with Chédiak-Higashi syndrome. (E, F) Neutrophils from a patient with specific granule deficiency. (G) Neutrophils from a patient with myeloperoxidase deficiency. The blue positive-staining cell is an eosinophil.

of a certain granule can be associated with deficiency of an entire pool of granules, such as specific granule deficiency. Both enzymatic assays and immunoassays are available to determine the cellular content of many of these granule constituents.

Principles and Interpretation of Laboratory Assessment

The cellular content of neutrophils can be determined by solubilization of a neutrophil pellet with 0.2% Triton X-100, followed by sonication to disrupt the cells and generate a homogeneous lysate. Analysis of the lysate using commercial immunoassays can identify deficiencies of certain granule contents. Diagnosis of myeloperoxidase deficiency can be confirmed by analysis of neutrophil lysates. Similarly, deficiency of both lactoferrin and neutrophil gelatinase (matrix metalloprotein-9 [MMP-9]) is indicative of specific granule deficiency, although interestingly, specific granule deficiency is also associated with a deficiency of the α-defensins (human neutrophil peptides 1–3), stored in the azurophilic granules.[18]

NEUTROPHIL ADHERENCE

Clinical Indications and Implications

Adherence of neutrophils to the endothelium is a prerequisite step to the migration of neutrophils into the tissues. Neutrophils isolated from patients with leukocyte adhesion defect-1 (LAD-1) who lack the common β_2 integrin subunit CD18 exhibit abnormal adherence to the endothelium[19] and therefore are not able to migrate efficiently into the surrounding tissues, often resulting in marked granulocytosis.[20] LAD-2 is a milder form of the disease, in which patients exhibit a defect in fucose metabolism and glycoprotein biosynthesis.[21] Neutrophils from patients with LAD-2 exhibit abnormal expression of the glycoprotein L-selectin and fail to roll along the endothelium. However, they do exhibit normal β_2 integrin–mediated adherence.

Principles and Interpretation of Laboratory Assessment

Adherence of neutrophils can be assessed by measuring binding to plastic using a 96-well plate either uncoated or coated with fetal bovine serum or a specific extracellular matrix (ECM) protein, such as fibrinogen or fibronectin. Endothelial cell monolayers harvested from human umbilical veins may serve as a more physiological substrate for the measurement of cell adhesion. Isolated neutrophils are preloaded with the cell permeant acetoxymethyl ester derivative of the fluorescent dye calcein (calcein-AM). Nonspecific esterases in the cytosol cleave the ester linkage, trapping the fluorescent probe in the cytosol. The labeled neutrophils are added to each well and incubated in the absence or presence of phorbol myristate acetate (PMA) to promote adherence through activation of the integrins. At the end of the incubation, the wells are washed three times to remove nonadherent cells. The fluorescence of each well is determined with a fluorescent microplate reader and compared with the fluorescence of a control well with a fixed number of fluorescent cells. As shown in the left panel of Fig. 94.2, under control conditions, fewer than 10% of the neutrophils adhere to plastic or to plastic coated with fetal bovine serum or fibrinogen. Treatment of normal neutrophils with PMA for 30 minutes results in the adherence of >90% of the neutrophils under all conditions. This adherence assay is valuable in the diagnosis of patients with leukocyte adhesion deficiency. As shown in the right panel of Fig. 94.2, neutrophils isolated from patients with LAD-1 generally exhibit <5% adherence under control conditions and do not increase adherence after treatment with PMA.

NEUTROPHIL CHEMOTAXIS

Clinical Indications and Implications

Neutrophil migration is a prerequisite for neutrophil accumulation at sites of inflammation. Patients with leukocyte chemotactic defects usually show recurrent skin abscesses and occasional life-threatening, invasive infections.

Principles and Interpretation of Laboratory Assessment

Chemotaxis *in vitro* is generally measured using a Boyden chamber. The Boyden chamber includes three components: a lower (chemoattractant) chamber, a nitrocellulose or polycarbonate filter layer, and an upper cell chamber. The lower compartments of the Boyden chamber are filled with a chemoattractant, such as formyl-methionyl-leucyl phenylalanine (fMLF; 10^{-8} M) or interleukin-8 (IL-8; 10^{-8} M). Alternatively, a rapid fluorescence-based measurement of neutrophil chemotaxis that uses a 96-well

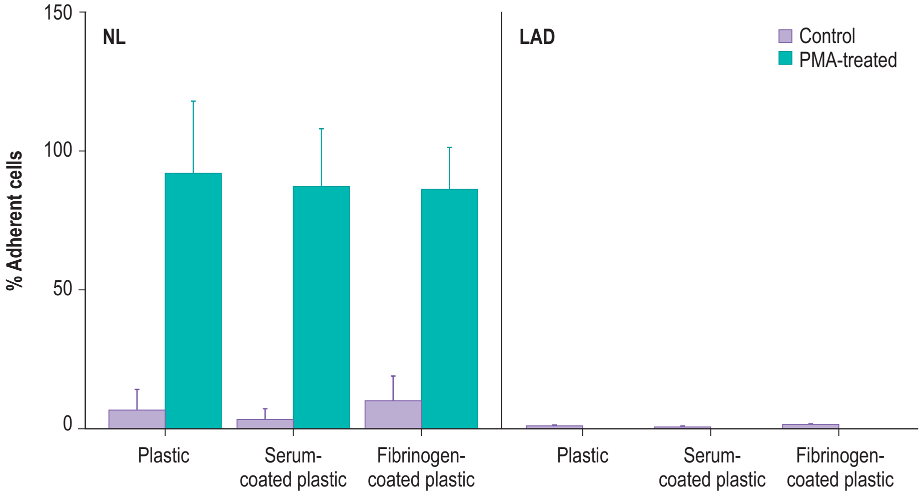

FIG 94.2 Adherence of Neutrophils to Plastic: Normal Versus Leukocyte Adhesion Deficiency. Neutrophils (1 × 10^7 cells/mL Hanks balanced salt solution [HBSS] without divalent cations) were preloaded with acetoxymethyl ester derivative of calcein (calcein-AM: 5 μg/mL) for 15 minutes at 37°C. The cells were washed twice and resuspended in HBSS/4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) with 2% bovine serum albumin (BSA) at a cell concentration of 2 × 10^6/mL. The wells of a 96-well plate were coated for 1 hour at 37°C with 32 μL of either buffer alone, fetal bovine serum, or fibrinogen (2.5 mg/mL). The wells were washed three times, and then cells were added to each well (160 μL/well, 3.2 × 10^5/well). After a 10-minute preincubation at 37°C, PMA (100 ng/mL) was added and the plate was incubated for 30 minutes at 37°C. The wells were then washed three times with HBSS/HEPES to remove nonadherent neutrophils. The percentage of adherent cells was determined by the ratio of the fluorescence of the well compared with the fluorescence of a known standard well. The panel (NL) on the left represents the data (mean ± standard deviation [SD]) from 22 normal subjects and the panel on the right represents the data from three patients with leukocyte adhesion deficiency.

disposable chemotaxis chamber,[22] that can be read in a fluorescence microplate reader, can be used. The lower chamber contains the chemoattractant and is separated from the cellular compartment by a filter. However, instead of a top chamber, the filter has a hydrophobic mask around each filter site that creates surface tension in the cell suspension and aligns the suspension on the hydrophilic filter located directly above the chemoattractant chamber. Calcein-labeled neutrophils are placed on top of the filter. The chemotaxis chamber is incubated for up to 60 minutes at 37°C. Nonmigrating neutrophils atop the filter are rinsed off with buffer, and then the plate is read in a fluorescence microplate reader. The number of migrating neutrophils can be determined by comparison of the fluorescence to a standard well with a known number of fluorescent neutrophils. Less than 5 × 10^6 fluorescent neutrophils are needed to determine neutrophil chemotaxis using several doses of the chemoattractants, fMLF, IL-8, C5a, and leukotriene B_4. The advantages of this assay are high sensitivity, rapid acquisition and analysis of data, and reduced labor in loading the cell suspension. The 96-well format also allows for multiple comparisons to be made under identical conditions.

Instrumentation, such as the EZ-TAXIScan, is now available to monitor chemotaxis temporally. By acquiring digital images over time and analyzing them using imaging software, the coordinates of individual cells can be determined. Changes in the distance (and velocity) in the direction of the chemoattractant (directed migration) and orthogonal to the direction of the chemoattractant (random migration) can be determined. Tracks of multiple cells can be anchored at the origin and displayed graphically (Fig. 94.3, top panels). Adding time as a dimension in the analysis of chemotaxis provides a mechanism to evaluate simultaneously both chemotactic and chemokinetic responses in neutrophils and to detect more subtle defects. Using buffer as a chemoattractant, the average cellular velocity vector in the direction of the chemoattractant and the average cellular velocity vector orthogonal to the direction of the chemoattractant are typically equivalent (Fig. 94.3, bottom panel). When using a chemoattractant (*e.g.,* fMLF, IL-8), typically there is marked increase in the average cellular velocity vector in the direction of the chemoattractant, but little change in the average cellular velocity vector orthogonal to the direction of the chemoattractant (see Fig. 94.3, bottom panel).

EXPRESSION OF SURFACE ANTIGENS

Clinical Indications and Implications

The expression of neutrophil membrane antigens is altered *in vivo* during exudation or after challenge with intravenous endotoxin. Flow cytometric analysis of adhesion molecules on the neutrophil cell surface can indirectly reflect neutrophil adhesion function. Patients with LAD-1 exhibit a deficit in the expression of the common β_2 integrin, CD18, resulting in deficiency in CD11a, CD11b, CD11c, and CD18[23] (Chapter 22).

Principles and Interpretation of Laboratory Assessment

The expression of cell surface antigens is determined on neutrophils stained with specific fluorescent monoclonal antibodies (mAbs) and analyzed by flow cytometric analysis. Neutrophils

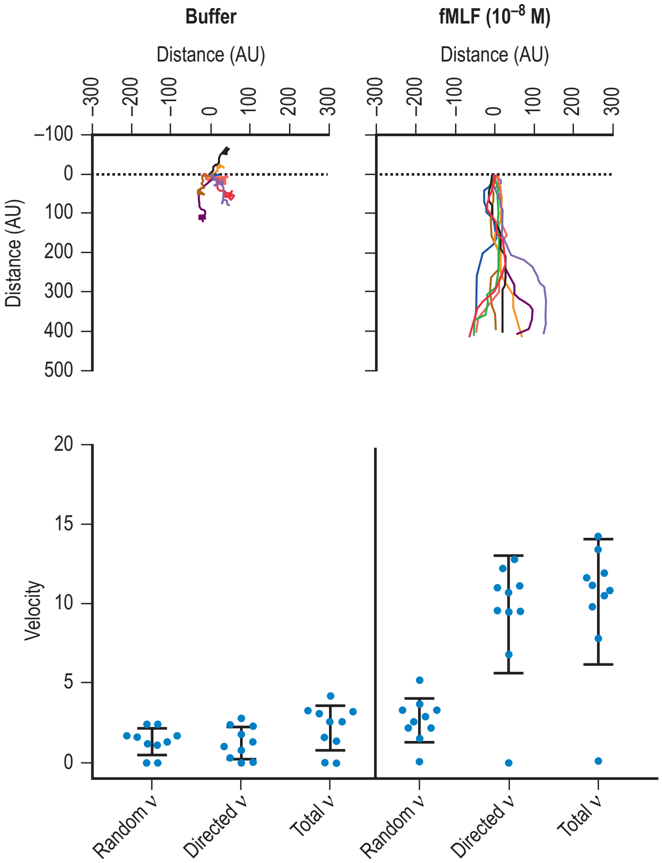

FIG 94.3 Analysis of Chemotaxis. In the top panel, neutrophils (1 µl of 2×10^6 cells/mL in Hanks balanced salt solution [HBSS] with divalent cations) were added to the "Cell" well of EZ-TAXIScan and either buffer (left column) or formyl-methionyl-leucyl-phenylalanine (fMLF; 1×10^{-8} M, right column) was added to the "Chemoattractant" well. The cells were incubated for 60 minutes and images were collected every 2.5 minutes. Using the acquired images, 10 randomly chosen cells were electronically tracked and the paths of the cells plotted with their position at t = 0 anchored at the origin. Presented in the bottom panel are scattergrams of the average velocities of the individual cells that were tracked in the top panel.

stained with nonspecific isotype antibodies are used to determine the nonspecific background staining. To determine the expression of circulating neutrophils and avoid artifacts induced by neutrophil isolation, an aliquot of whole blood can be stained with the appropriate antibody before lysis of the erythrocytes. During flow cytometric analysis, the neutrophils are easily differentiated using their forward light scatter and right angle light scatter to gate on the neutrophil population. Since very little blood is needed (100 µL) for each antigen, neutrophils can be stained with a panel of antibodies to many relevant surface antigens so that a more complete representation of surface antigen expression on neutrophils can be obtained. The panel should include the β_2 integrins (CD11a, CD11b, CD11c, and CD18); selectins (CD62L); Fcγ receptors I, II, and III (CD64, CD32 and CD16); leukosialin (CD43); the common leukocyte antigen (CD45); and distinct surface markers for the granules—carcinoembryonic antigen-related cell adhesion molecule 8 (CEACAM8, or CD66b), a GPI-anchored glycoprotein family member stored in the specific granules, and lysosomal-associated membrane protein 3 (LAMP-3, or CD63), stored in the azurophilic granules. During exudation, the expression of CD11b and CD18 is increased over that observed in peripheral neutrophils, whereas the expression of CD43 (leukosialin) and CD62L is markedly reduced.

The antibody 7D5 recognizes an extracellular epitope of gp91*phox* and can be used to identify surface expression of gp91*phox* as well as mobilization of latent pools of gp91*phox* stored in the specific granules. Flow cytometric analysis of neutrophils stained with 7D5 can often be used to identify patients with X-linked chronic granulomatous disease (CGD) (no 7D5 staining) and X-linked chronic carriers of CGD (mosaic pattern of staining), particularly in patients where the number of cells available for testing is limited.

The expression of surface antigens can also be used to assess the responsiveness of neutrophils to particular ligands, such as fMLF and LPS. As shown in Fig. 94.4, neutrophils isolated from a patient who has a genetic defect in IL-1 receptor–associated kinase-4 (IRAK-4)[24] exhibit abnormal regulation of surface antigen expression to LPS but exhibit normal regulation of surface antigen expression to fMLF. Antigen expression can be upregulated because of translocation of latent antigen to the plasma membrane or downregulated because of either internalization or shedding of the antigen.

NEUTROPHIL DEGRANULATION

Clinical Indications and Implications

The proteases, acid hydrolases, and inflammatory mediators released from storage granules in the neutrophils can mediate bacterial killing, tissue damage, healing, and immune regulation. Lactoferrin that is released from specific granules can chelate iron, resulting in a bactericidal or bacteriostatic effect. Elevation of plasma lactoferrin is an indication of intravascular activation and degranulation of neutrophils.

Principles and Interpretation of Laboratory Assessment

Stimulation of neutrophils with various secretagogues can result in the release of granular enzymes into the extracellular fluid. Treatment of the neutrophils with cytochalasin b (5 µg/mL) disrupts microfilament assembly and facilitates the release of both specific and azurophilic enzymes. Since stimulation of neutrophil degranulation is often accompanied by ROS generation and oxidative inactivation of enzymes, both the cell supernatant fluid and the cell pellet should be analyzed to determine the percentage of enzyme released. To differentiate degranulation from cell lysis, release of the cytosolic enzyme lactate dehydrogenase should be monitored simultaneously.

The release of azurophilic granules can be assessed by determining the levels of myeloperoxidase or elastase. CD63 is also found in the membrane of azurophilic granules and migrates to the neutrophil surface after stimulation with fMLF in the presence of cytochalasin b. The release of specific granules can be assessed by determination of lactoferrin levels by using an enzyme-linked immunoassay. The carcinoembryonic antigen CD66b is found on the neutrophil surface and the specific granules, and its expression on the surface of the neutrophils is increased after stimulation with fMLF or LPS. The secretory granules usually contain proteins that are translocated into the membrane from cytosol during degranulation. Detection of the constituents of secretory granules can be assessed by flow cytometric analysis of the change in expression of surface proteins, such as adhesion molecules, and cytochrome b_{558} of the NADPH oxidase.

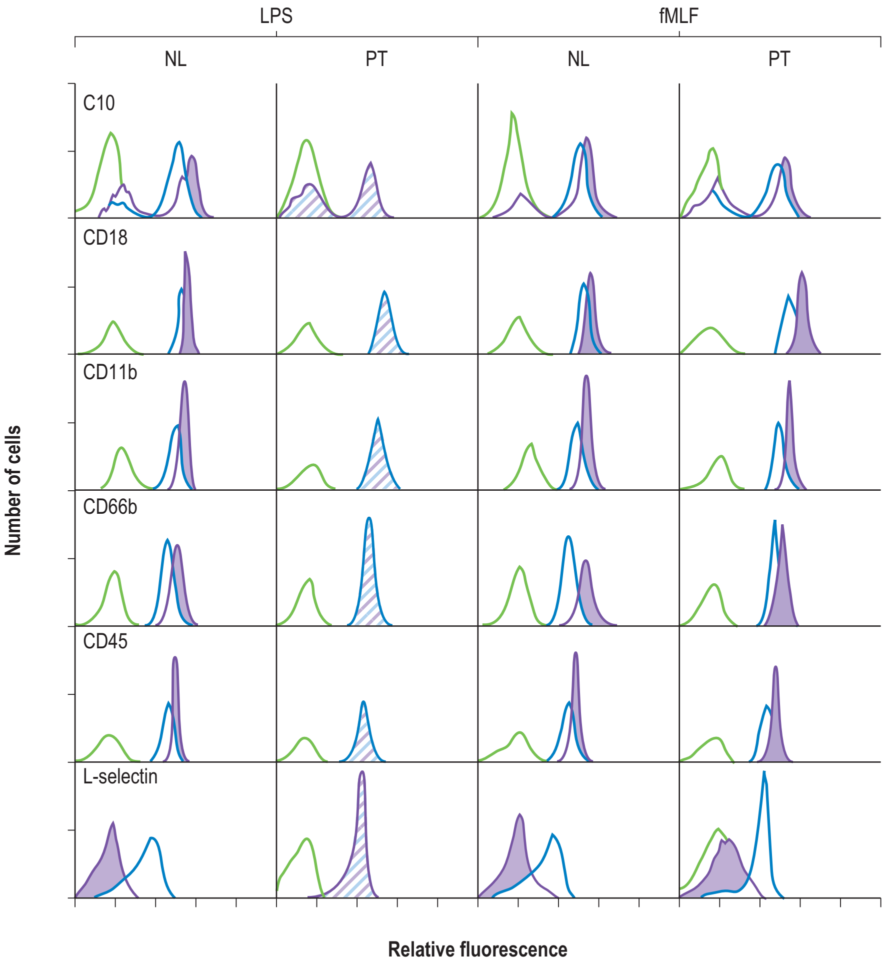

FIG 94.4 **Upregulation of Neutrophil Surface Antigen Expression.** Neutrophils (2.5 × 10^6/mL Hanks balanced salt solution [HBSS] + 10% AB sera) isolated from a normal subject (NL) or from a patient with an interleukin-1 receptor-associated kinase-4 (IRAK-4) mutation (PT) were treated with either lipopolysaccharide (LPS; 100 ng/mL) or formyl-methionyl-leucyl-phenylalanine (fMLF; 0.1 μM) for 30 minutes at 37°C. The cells were washed and stained with C10 (an antibody that demonstrates neutrophil heterogeneity), CD18, CD11b (antibodies to β2 integrins), CD66b (a specific granule marker), CD45 (the common leukocyte antigen), and L-selectin. The green lines represent the isotype control, blue lines represent control neutrophils, and purple lines represent stimulated cells. Differences between control and stimulated cells have been shaded. (From Kuhns DB, Long Priel DA, Gallin JI. Endotoxin and IL-1 hyporesponsiveness in a patient with recurrent bacterial infections. J Immunol 1997;158:3959, with permission of the American Association of Immunologists, Inc.)

GENERATION OF REACTIVE OXYGEN SPECIES

Clinical Indications and Implications

The release of ROS, such as $O_2^{\bullet}$ and H_2O_2, is an important component of the bactericidal machinery of a neutrophil. Neutrophils isolated from patients with CGD have a defect in the NADPH oxidase and are unable to generate ROS, resulting in an O_2-dependent bactericidal defect. The production of ROS has become an important tool to perform risk assessment in patients with CGD. Patients with the lowest ROS generation (<1% of normal generation) have lower survival than patients with higher ROS generation (3–10% of normal). Moreover, survival in CGD is a continuous function of ROS production, suggesting that therapeutic interventions that result in an increase in ROS generation should incur a survival benefit to patients with CGD.[25]

CLINICAL PEARLS

Reactive Oxygen Species (ROS) in Chronic Granulomatous Disease (CGD)

- Neutrophil ROS production, the primary determinate in diagnosis of patients with CGD, ranges from 0.1% to 27% of that observed in normal subjects.
- In addition, survival in CGD is strongly associated with residual ROS production as a continuous variable, and is independent of the specific protein defect.
- ROS production is an important, early indicator of overall risk in CGD.
- In addition, small increases (as little as 3–5% of normal) in residual neutrophil ROS production may confer a survival benefit.
- Careful monitoring with detection of even small increases in ROS may be an important indicator of clinical efficacy during therapeutic intervention.

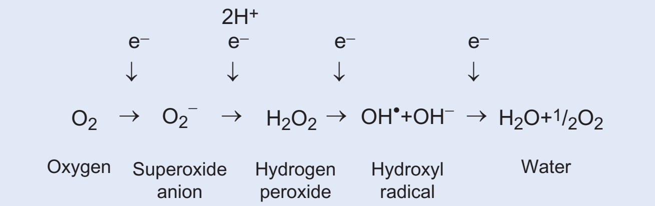
Principles and Interpretation of Laboratory Assessments

The nitroblue tetrazolium (NBT) test is a qualitative assay of ROS production. Either whole blood or isolated neutrophils are mixed with NBT in a chamber slide and stimulated with PMA for 15–30 minutes at 37°C. The neutrophils are allowed to settle on the slide. The slide is air-dried, counterstained with 0.1% safranin, and examined under a microscope. The NBT test yields a visual record of the reduction of the NBT dye to the insoluble, blue-black deposits of formazan. Normal neutrophils, but not neutrophils from patients with CGD, reduce the yellow dye to black-brown-blue aggregates in the cells. Because of the random inactivation of the X chromosome, X-linked carriers of CGD exhibit both NBT^+ and NBT^- neutrophils. The percentage of NBT^+ neutrophils in X-linked carriers of CGD ranges from 5 to 95%. The drawback of the NBT test is the need for manual counting to obtain an accurate reflection of the percentage of positive cells. An alternative to the NBT test is a flow cytometric assay using the dye dihydrorhodamine–123 (DHR-123).[26] Neutrophils are loaded with the nonfluorescent dye and then stimulated with PMA for 15 minutes at 37°C. The H_2O_2 produced oxidizes the dye and results in increased fluorescence, which is detectable with a flow cytometer. The assay is dependent on endogenous myeloperoxidase in the primary granules. Catalase is added to prevent cell-to-cell diffusion of H_2O_2. Since dye is localized to the cytoplasm and catalase is present in the extracellular fluid, the DHR-123 assay detects the intracellular production of ROS. As shown in Fig. 94.5, stimulation of normal neutrophils (Fig. 94.5A) with PMA results in a two-log shift in the fluorescence intensity. Neutrophils from an X-linked carrier of CGD (see Fig. 94.5B) exhibit mosaicism with a negatively stained (abnormal) population and a brightly stained positive population. Neutrophils from a patient with X-linked CGD that lack $gp91^{phox}$ (Fig. 94.5C) express little increase in fluorescence while neutrophils from a patient with a deficiency in $p47^{phox}$ (see Fig. 94.5D) exhibit a slight increase in fluorescence. The major advantages of the DHR-123 assay are the sensitivity, the signal-to-noise ratio, and the ease of counting a large number of cells. Moreover, it has been shown that the DHR-123 assay yields reliable results on ethylenediaminetetraacetic acid (EDTA) or heparin-treated blood samples that have been stored overnight. In general, more than 90% of the neutrophils from the control blood samples will exhibit increased DHR-123 fluorescence. For this same reason, however, overnight samples should not be used to rule out X-linked heterozygosity, since a highly lyonized CGD carrier (>90%) could yield similar results.

The production of $O_2^{\bar{\bullet}}$ can be detected using the reduction of cytochrome c. Because $O_2^{\bar{\bullet}}$ causes a one-to-one stoichiometric reduction of ferricytochrome c to ferrocytochrome c, the resultant increase in the absorption spectrum at 550 nM can be used to quantitate the production of $O_2^{\bar{\bullet}}$. Superoxide dismutase is added to an identical tube to control for the nonspecific reduction of cytochrome c. However, since cytochrome is not permeable to the cells, the detection of $O_2^{\bar{\bullet}}$ is limited to that released into the extracellular milieu. Neutrophils isolated from normal volunteers produce 0.42 ± 0.67 nmol/10^6 neutrophils/10 min under resting conditions; treatment with PMA results in 35.92 ± 11.92 nmol/10^6 neutrophils/10 min (Fig. 94.6). An estimate of normal $O_2^{\bar{\bullet}}$ production over 60 minutes can be obtained by reducing the number of neutrophils in the assay to 2×10^5. Neutrophils isolated from patients with CGD produce little, if any, $O_2^{\bar{\bullet}}$ in response to PMA in 10 minutes (Fig. 94.6). However, some patients with autosomal forms of CGD have low, but detectable $O_2^{\bar{\bullet}}$ production in 60 minutes. Neutrophils isolated from X-linked heterozygous carriers of CGD can yield a full spectrum of $O_2^{\bar{\bullet}}$ production, whereas neutrophils from autosomal recessive carriers of CGD generally yield a normal response (see Fig. 94.6). Although the detection of $O_2^{\bar{\bullet}}$ by reduction of cytochrome c is useful in the diagnosis of patients with CGD, it cannot be used in the diagnosis of carriers because of the wide spectrum of responses that result from the degree of X chromosome lyonization.

KEY CONCEPT

Reactive Oxygen Species



The stepwise reduction of oxygen (O_2) leads to reactive oxygen species and finally to water (H_2O).

Studies have shown that $O_2^{\bar{\bullet}}$ determinations sufficiently reliable to diagnose CGD can be obtained from neutrophils isolated from heparinized whole blood that has been stored overnight. Hence, analyses can be performed on blood samples shipped by overnight express. A normal control blood sample should accompany the sample to ensure adequate shipment handling. By 48 hours of storage, however, there are marked reductions in the PMA response, and the data are no longer valid.

An alternative assay to measure ROS production is luminol-enhanced chemiluminescence. This versatile assay, in addition to its quick and easy setup, offers the capability to test several different subjects and stimuli on the same plate using reduced numbers of cells while providing high sensitivity. The luminescence readings are taken every 1–5 min for up to 2 hours, and data are expressed as relative light units (RLUs). Different stimuli exhibit different kinetics (*e.g.,* fMLF induces a rapid respiratory burst that decays quickly, whereas PMA [20–100 ng/mL] induces a peak of luminescence within 5–15 minutes that slowly decays by 2 hours). Results from normal subjects and patients can be assessed simultaneously and monitored kinetically or using the area under the curve (AUC). Luminol-enhanced chemiluminescence is a measure of both intracellular and extracellular ROS production, although it may not detect them with equivalent efficiency. Addition of superoxide dismutase significantly reduces both peak height and AUC after stimulation with PMA, suggesting that at least a portion of the response can be attributed to $O_2^{\bar{\bullet}}$. Typically, patients with CGD who are deficient in $gp91^{phox}$ have little to no detectable luminescence in this assay; however, as observed with the ferricytochrome c assay, patients with CGD who are deficient in $p47^{phox}$ have detectable luminescence that becomes most evident at later readings (40–80 minutes) (Fig. 94.7).

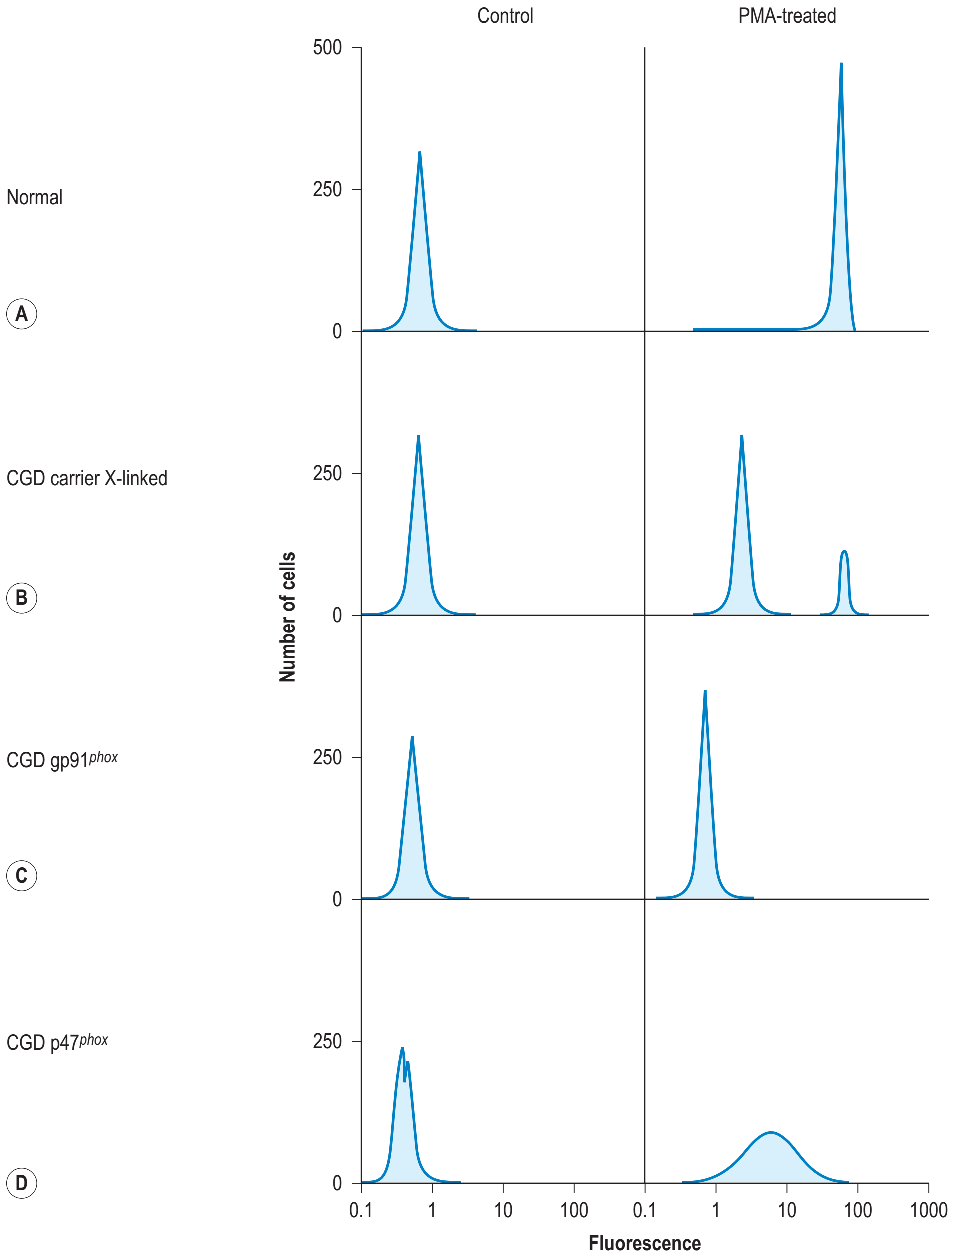


FIG 94.5 Flow Cytometric Analysis of Dihydrorhodamine (DHR) Staining. Whole blood (1.2 mL with ethylenediaminetetraacetic acid [EDTA] as anticoagulant) collected from a normal subject (A), an X-linked chronic granulomatous disease (CGD) carrier (B), a gp91*phox* CGD patient (C), and a p47*phox* CGD patient (D) was lysed by using an ammonium chloride–potassium bicarbonate solution. The remaining leukocytes were resuspended in HBSS and incubated with DHR-123 (100 μM) and catalase (50 μg/ml) for 5 minutes at 37°C. The cells were then incubated an additional 15 minutes at 37°C with either buffer (control) or phorbol myristate acetate (PMA; 400 ng/mL). The cells were immediately analyzed by flow cytometric analysis. Neutrophils were gated using forward light scattering and right-angle light scattering. The analyses presented represent 5000 events within the gated area.

WESTERN BLOT ANALYSIS OF NADPH OXIDASE PROTEIN SUBUNITS

Clinical Indications and Implications

The NADPH oxidase consists of two membrane components (p22*phox* and gp91*phox*), three cytosolic components (p47*phox*, p67*phox*, and p40*phox*), and several guanosine triphosphate (GTP)–binding proteins. CGD is characterized by defects in any one of four of these components—p22*phox* (≈5% of patients with CGD), p47*phox* (≈25% of patients with CGD), p67*phox* (≈5% of patients with CGD), and gp91*phox* (remaining 65% of patients with CGD).

Principles and Interpretation of Laboratory Assessments

The severity of CGD can be related to the specific protein defect. Determination of the specific protein defect in CGD by Western blot analysis also provides direction for determination of the

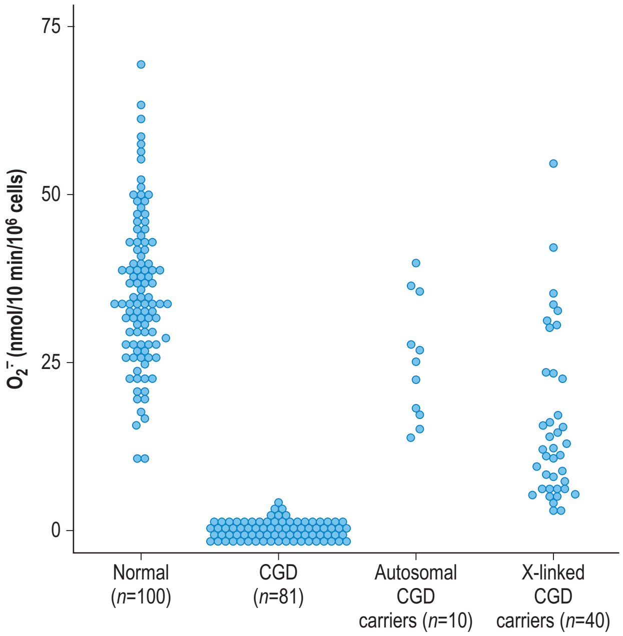

FIG 94.6 $O_2^{\bullet -}$ Generation From Normal Subjects, Patients With Chronic Granulomatous Disease (CGD), and Carriers of CGD. Neutrophils (1 × 10^6/mL Hanks balanced salt solution [HBSS]) were incubated in the presence of 100 µM cytochrome c with phorbol myristate acetate (PMA; 100 ng/mL) for 10 minutes at 37°C. The reaction was terminated by centrifugation at 4°C. Reduction of cytochrome c was monitored at an analytical wavelength of 549.5 nm and a micromolar extinction coefficient of 0.0211. An identical tube containing superoxide dismutase (100 µg/mL) served as a blank.

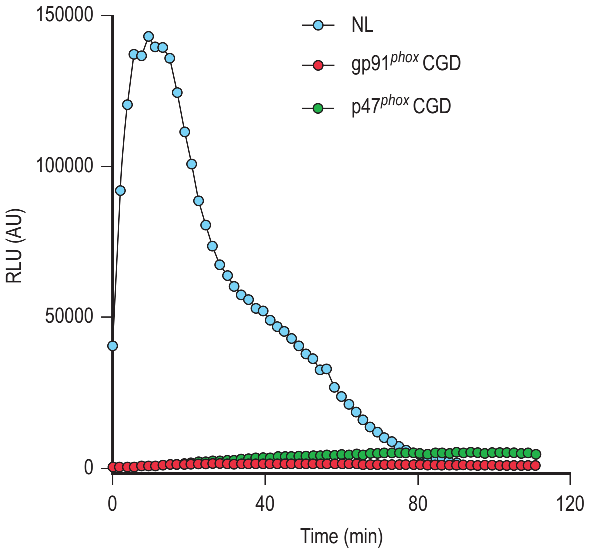

FIG 94.7 Luminol-Enhanced Chemiluminescence. Neutrophils (1 x 10^5/200 µL) were preloaded with luminol (100 µM) for 10 min at 37°C. At t = 0, either buffer or phorbol myristate acetate (PMA; 100 ng/mL) was added and luminescence was monitored for 2 hours, with readings recorded every 2 minutes. Note that at later readings, neutrophils from a patient with p47*phox* deficiency had increased luminescence compared with neutrophils from a patient with chronic granulomatous disease (CGD) gp91*phox* deficiency.

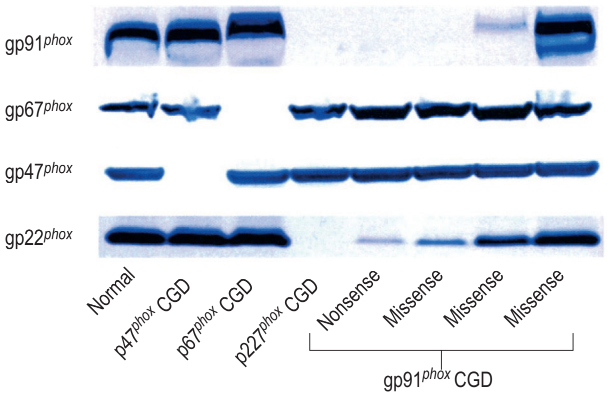

FIG 94.8 Determination of Nicotinamide Adenine Dinucleotide Phosphate (NADPH) Oxidase Protein Defect by Western Blot Analysis. Frozen, diisopropylflurophosphate (DFP)–treated neutrophil pellets (5 × 10^6 cells) were resuspended in polyacrylamide gel electrophoresis (PAGE) sample buffer and sonicated to break up the DNA. One million cell equivalents were loaded into each lane (10% PAGE gels for p47*phox* and p67*phox*, 4–12% gradient PAGE gels for p22*phox* and gp91*phox*). A validated normal control was run on each gel for quality control. The gels were transferred to nitrocellulose, blocked with 5% powdered milk, and incubated overnight with specific antibodies to the phox proteins. The blots were washed, incubated with peroxidase-labeled secondary antibody, and developed with a color reagent. The blots were scanned for permanent storage, and a composite figure was created by using the relevant bands from each blot. The lanes are identified by the specific protein defect and, for gp91*phox*, the type of mutation. CGD, chronic granulomatous disease.

specific genetic defect and enables appropriate genetic counseling for the extended family. A validated normal control is included on each gel for band identification and intensity comparisons. In addition, a control sample from a patient with a known mutation in gp91*phox* CGD is included on each blot to ensure adequate development of p22*phox*. Typical phox protein band patterns are presented in Fig. 94.8. Patients with CGD who have mutations in p47*phox* are Western blot negative. Patients with CGD who have mutations in p67*phox* are generally Western blot negative; however, we have analyzed one patient with a missense mutation in p67*phox* who was Western blot positive. Because p22*phox* and gp91*phox* exist as a membrane complex, patients with a defect in p22*phox* are generally Western blot negative for both p22*phox* and gp91*phox*. In contrast, defects in gp91*phox* yield more variable results. In general, patients with nonsense defects in gp91*phox* exhibit low but detectable levels of p22*phox*. Patients with missense mutations in gp91*phox* that yield detectable gp91*phox* protein exhibit proportionately higher levels of p22*phox*. Neutrophils isolated from overnight samples can be used to diagnose p47*phox* deficiency because of the stability of the protein. However, detection of other phox protein defects in overnight samples can be more problematic because of proteolysis of p67*phox* and the gp91*phox*–p22*phox* complex.

CONCLUSIONS

Our understanding of neutrophil biology is undergoing significant changes. Long-standing axioms are being challenged. Chakravarti et al. suggested that treatment of neutrophils with a cocktail of cytokines can reprogram a phenotypically distinct subset of neutrophils with increased survival and altered function.[27] Rodriguez et al. have shown that patients with renal cancer have a subset of lighter density neutrophils that colocalize with mononuclear cells atop the density cushion and appear to be phenotypically "activated";[28] moreover, these lighter-density neutrophils are capable of suppressing T-cell proliferation through a mechanism dependent on arginase-1 stored in the gelatinase granules, a novel function of neutrophils.

ON THE HORIZON

There is growing evidence that neutrophils may be derived from organs other than bone marrow, such as the lung, liver, and, particularly, spleen. Recently, it has been suggested that the spleen may serve as a reserve site for "emergency myelopoiesis" during infection. Other studies suggest that c-kit$^+$ myeloid precursors from blood migrate to a site of cutaneous infection, where they proliferate and form mature polymorphonuclear neutrophils (PMNs). These findings are based on murine studies and raise the following questions:

- Are these extramedullary neutrophils found in humans?
- Are there specific biomarkers that distinguish them from their bone marrow–derived circulating counterparts?
- Do they have functionality that is different from circulating neutrophils?

Much of our current understanding of neutrophil biology has developed from the study of genetic immunodeficiencies. Whether there are immunodeficiencies that result from defects in these recently discovered pathways has yet to be determined.

MULTIPLE-CHOICE QUESTIONS

1. Results from laboratory testing show that neutrophils from a patient exhibit a negative dihydrorhodamine (DHR) analysis but exhibit normal/supranormal production of $O_2^{\bar{\bullet}}$ by cytochrome c reduction. What is the MOST likely reason(s) for these results?
   A. The patient probably has myeloperoxidase (MPO) deficiency; the discrepancy in these test results should be resolved by Kaplow peroxidase staining of the polymorphonuclear neutrophil (PMN) preparation and/or MPO enzyme-linked immunosorbent assay (ELISA).
   B. The patient has no immune defect since the $O_2^{\bar{\bullet}}$-dependent ferricytochrome c assay falls with the normal range.
   C. The patient has chronic granulomatous disease (CGD).
   D. None of the above.

2. Why are neutrophils treated with the fluorescent dye, calcein-AM, in the adherence assay?
   A. Calcein is needed to activate the cells.
   B. Calcein is needed to activate the integrins.
   C. The calcein fluorescence of the adherent cells can be quantified with the use of a fluorescent plate reader.
   D. None of the above.

3. The DHR analysis of neutrophils stimulated with phorbol myristate acetate (PMA) from a patient yielded a broad peak of fluorescence with a moderate shift to the right that did not fall within the normal range. What is the MOST likely interpretation of this finding?
   A. The subject most likely has CGD with a defect in p47*phox*.
   B. The subject is most likely a carrier of gp91*phox* deficient CGD.
   C. The subject most likely has CGD with a defect in gp91*phox*.
   D. The subject is most likely normal.

4. When performing Western blot analyses for the detection of components of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, what is the MOST important reason to run a control from a patient with a known mutation in gp91*phox*?
   A. It is performed to serve as validation of the assay.
   B. It is performed to ensure adequate development of p22*phox* for the correct identification of the impaired protein of the membrane component.
   C. It is only important to run a control from a normal subject for band identification and intensity comparisons
   D. Only molecular weight markers are needed to run to serve as band identification.

Assessment of Human Allergic Diseases

Robert G. Hamilton

Human allergic disease comprises a spectrum of immunoglobulin E (IgE)–mediated immediate-type hypersensitivity reactions that manifest as reactions in skin (urticaria, dermatitis), the respiratory tract (asthma, rhinitis, or sinusitis), eyes (conjunctivitis), the gastrointestinal (GI) tract (abdominal pain, bloating, vomiting, diarrhea), and, in their most extreme condition, systemic anaphylaxis. These reactions are precipitated by exposure of a genetically predisposed and sensitized (IgE antibody-positive) individual to a variety of environmental substances that are ubiquitous and usually well tolerated by most healthy individuals. This chapter reviews the principles and performance characteristics of analytical methods used in the diagnosis and management of individuals with allergic disease. It examines *in vivo* and *in vitro* methods for the quantification of total and allergen-specific IgE.

BIOLOGICAL PROPERTIES OF IGE

In 1921, Prausnitz and Küstner (PK)[1] reported that an intradermal (ID) injection of serum from an allergic individual into the skin of an unsensitized (nonallergic) individual, followed 24 hours later by injection of specific antigen into the same skin site, induced local itching and swelling surrounded by a zone of erythema. This passively transferred allergic reaction, or *PK reaction,* reached a maximum within 10 minutes, persisted for about 20 minutes, and gradually disappeared. The antibody mediating this reaction was shown to be thermolabile, losing its sensitizing activity after heating serum at 56°C for several hours. In 1967, this antibody was identified as a fifth human immunoglobulin isotype and designated as IgE.[2-4]

Total serum IgE concentrations are the lowest of the five human immunoglobulin isotypes (0–0.0001 g/L; 0.004% of the total adult serum immunoglobulin).[5] Approximately 50% of IgE is localized in the extravascular space. Its short biological half-life of 1–5 days in peripheral blood is primarily the result of a relatively high fractional catabolic rate (71% of the intravascular pool catabolized/day). IgE does not pass the placenta or activate the classical complement pathway. Its reaginic (mast-cell sensitizing) activity is dependent on its ability to bind to the α chain of the high-affinity IgE Fc-ε receptor (α-FcεRI) that resides on the membrane surface of basophils and mast cells. The interaction between IgE Fc and the α-FcεRI is blocked by the therapeutic subcutaneous administration of anti-IgE therapeutics, such as omalizumab (a humanized IgG1-κ anti-IgE Fc), as discussed below.

CLINICAL IMPORTANCE OF TOTAL SERUM IGE

The concentration of IgE in the serum is highly age dependent.[5] Cord serum IgE concentrations are low, usually <2 kU/L (<4.88 µg/L; 1 kU = 2.44 µg and 1 IU = 2.44 ng). Serum IgE levels progressively increase in healthy children up to the age of 10–15 years and gradually decline in an age-dependent manner from the second to the eighth decades of life. Infants with atopia have an earlier and steeper rise in serum IgE levels during their early years compared with age-matched controls without atopia.[6]

Clinically, a patient's total serum IgE level should be evaluated against reference intervals established with sera from an age-stratified, healthy skin test-negative (nonatopic) population.[6] Many clinical laboratories define a total serum IgE >100 kU/L (240 ng/mL) as a general demarcation into the atopic region.[7] After age 14 years, serum IgE levels >333 kU/l (>800 µg/L) are abnormally elevated and strongly associated with atopic disorders, such as allergic rhinitis, extrinsic or allergic asthma, and atopic dermatitis. Extreme elevations in serum IgE are common in parasitic infections and are necessary for the diagnosis of the hyper-IgE (Job's) syndrome. Low total IgE levels <25 kU/L in individuals with asthma suggest that IgE-mediated mechanisms play an insignificant role in the pathogenesis of their condition. Low total serum IgE levels thus support the diagnosis of nonallergic (intrinsic) asthma and help exclude allergic bronchopulmonary aspergillosis. There is extensive overlap between IgE levels in atopic and nonatopic populations,[6-9] which means that an elevated serum IgE can be useful in confirming the clinical diagnosis of allergic respiratory or skin diseases, but a low or normal value does not eliminate the possibility of an IgE-mediated mechanism. For instance, a group of adults with allergic asthma had a mean serum IgE level of 1589 ng/mL (range 55–12 750 ng/mL). In contrast, approximately 90% of patients with atopic dermatitis had elevated total serum IgE levels (mean 978 kU/L; range 1.3–65,208 kU/L). Parasitic infections, selected immunodeficiency states, cancer (Hodgkin disease, bronchial carcinoma), rheumatoid arthritis, liver disease, and atopic dermatitis (eczema) are other disease states that have been associated with a dysregulation of total serum IgE levels. The total serum IgE must therefore be interpreted within the relevant clinical context for each patient.

Because of the overlap between individuals with atopia and those without, total serum IgE measurements have been largely replaced in the routine diagnosis of allergic disease by the quantification of allergen-specific IgE antibody. However, quantification of total serum IgE has remained important for computing the therapeutic dose of anti-IgE. Omalizumab is a recombinant, humanized IgG1-κ monoclonal antihuman IgE Fc drug that specifically binds to the region on the ε heavy chain that interacts with α-FcεR1.[10,11] It is used to treat moderate to severe persistent allergic asthma and chronic idiopathic urticaria by blocking IgE binding to the α-FcεR1. The binding of omalizumab to IgE *in vivo* reduces both the number of free IgE molecules able to interact with the α-FcεR1 and the number of α-FcεR1 receptors on the surface of effector cells. The consequence is a reduction in mediator release and allergy symptoms following allergen exposure.[10,11]

CLINICAL IMPORTANCE OF ALLERGEN-SPECIFIC IGE

In contrast to total serum IgE, the presence of allergen-specific IgE antibody on the surface of circulating basophils or skin mast cells or in the serum is highly predictive of an individual's propensity to exhibit an allergic response following reexposure to that allergen. Before its identification as a novel immunoglobulin, IgE was only detectable with *in vivo* bioassays (skin test, bronchial or nasal provocation tests). Purification of IgE myeloma protein and the subsequent production of antisera specific for IgE led to the development of the first *in vitro* assay (radioallergosorbent test [RAST]) for the detection of allergen-specific IgE antibody in serum.[4,12,13] Since then, nonisotopic autoanalyzer variants based on the original noncompetitive cellulose paper disc solid-phase RAST design have been widely used in clinical immunology laboratories throughout the world.[13,14] These assays, discussed below, involve an immobilized allergen containing reagent that binds allergen-specific antibody from human serum and an enzyme conjugated anti-IgE the detects bound IgE antibody.

Historical studies have compared the diagnostic performance (sensitivity and specificity) of *in vivo* and the *in vitro* assays in the diagnosis of human allergic disease. These intermethod comparisons have shown that the presence of IgE antibody as measured by serological immunoassay methods usually agrees well with the presence of IgE detected in leukocyte and mast-cell histamine release assays, and provocation tests, such as the skin test, food challenge, and inhalation provocation test.[15,16] However, these early studies emphasize that the presence of IgE antibody as detected either *in vivo* or *in vitro* is at best a confirmatory measurement for sensitization.[17] IgE antibody is necessary but not sufficient for induction of an allergic symptom. It is considered an important risk factor in the diagnosis of allergic disease that supports a patient's medical, family, and environmental histories of a temporal association between allergic symptoms and allergen exposure. The clinical importance of differences in diagnostic sensitivity between skin test and serological detection of IgE antibody may be less important for patients with allergies to inhaled (pollen, dust mite, and epidermal) allergens than in those facing life-threatening anaphylactic reactions caused by *Hymenoptera* stings and certain drugs. In these latter cases, skin tests are preferable to *in vitro* immunoassay analyses for the detection of allergen-specific IgE antibodies.[16,18] Immunoassays of IgE antibody in serum can, however, be helpful in cases where the patient has taken antihistamines, β-receptor stimulants, or high-dose steroids, which can reduce the *in vivo* provocation test's measured response in children, pregnant women, and older patients, in whom skin testing may not be well tolerated and when dealing with allergens (*e.g.*, foods, molds) where commercial extracts can be highly variable or labile.[13,16]

CLINICAL HISTORY

The diagnosis of human allergic disease is driven principally by the patient's clinical history in which objective evidence is collected that an allergic reaction has occurred following exposure to a known or suspected allergen source. During the history, a number of factors need to be considered.[16] These include the patient's symptom characteristics (location, reproducibility, severity, duration, delay time from appearance following allergen exposure), atopic factors (personal and family histories, age of onset, infantile atopic dermatitis), opportunity for sensitization (geography, seasons, duration of exposure, prior exposures, employment, and hobbies), specificity of allergen triggers, and comorbidities (*e.g.*, nasal polyps, recurrent sinusitis, chronic obstructive pulmonary disease [COPD]). From the history, an *a priori* or pretest probability or likelihood of allergic disease is derived, and this determines whether or not confirmatory IgE antibody testing for sensitization is warranted.

DIAGNOSTIC METHODS

A combination of *in vivo* provocation and *in vitro* laboratory tests may be used to confirm sensitization and provide support for the clinical diagnosis of allergic disease. The actual tests selected depend on the nature of the disease process (*e.g.*, allergic asthma, urticaria/angioedema, rhinitis/sinusitis, or anaphylaxis) and the suspected allergen triggers (*e.g.*, aeroallergens, venoms, drugs, foods) under investigation. In making a decision about which diagnostic test to perform, clinicians start by searching for information on the diagnostic sensitivity and specificity of each confirmatory test. The true *diagnostic sensitivity* or ability of each test to detect IgE antibody in the presence of allergic disease and *diagnostic specificity* or ability of the test to not detect IgE antibody in health (absence of allergic disease) are difficult to determine definitively. Not only are there a myriad of assay methods, diverse techniques (*e.g.*, skin testing), reagents (extracts and molecules) and grading, interpolation, and interpretation methods, but most importantly, there is a general absence of gold standard methods for defining the presence of allergic disease. For this reason, results of the confirmatory tests need to be viewed as additional risk factors and tests for sensitization, rather than definitive indicators of disease.[17] In the end, the choice of the confirmatory test is a matter of clinical judgment.

INITIAL CLINICAL LABORATORY TESTS

Following the collection of a medical history and performance of a physical examination, the patient who is suspected of having allergic disease may undergo several preliminary blood tests. A complete blood count (CBC), and/or a total blood eosinophil count, if performed, should be obtained before any systemic corticosteroids or epinephrine is administered. A normal whole blood eosinophil level ranges from 0 to 500 cells/mm^3. Children generally have higher normal levels (mean 240 cells/mm^3 95% confidence interval [CI] = 0–740 cells/mm^3), with peak levels occurring at 4–8 years of age. Most clinical laboratories consider a differential white blood cell (WBC) count with an eosinophil proportion >5–10% of the total WBC count to be abnormal. Blood, sputum, and nasal secretion eosinophilia is characteristic of asthma, whether or not IgE-mediated allergic processes are present. In a bronchitic sputum specimen, neutrophils predominate. A neutrophilic nasal discharge is characteristic of sinusitis. Other laboratory tests that may be ordered, as indicated, include pulmonary function tests and a chest X-ray or sinus computer tomography (CT) scan.

IN VIVO PROVOCATION TESTING

Both the skin test and nasal/bronchial/GI provocation tests are useful *in vivo* diagnostic tools for the confirmation of immediate-type hypersensitivity reactions associated with allergic disease. They can also allow the identification of offending allergens in an allergy patient's workup for avoidance, or management with pharmacotherapy, immunotherapy or anti-IgE therapy.

Skin Tests

Historically, Guerin and Watson[19] described a three-phase skin response during an immediate-type skin test reaction following the administration of a stimulus (allergen or histamine-positive control). First, a bluish-white area appears that involves the constriction of capillaries and that typically disappears within minutes. Second, an erythematous peripheral halo or flare appears as a result of arteriole dilatation. Finally, a circular urticarial papule or wheal is observed, as a result of extravasation of plasma into the skin. The response is generally maximal by 15–20 minutes. The immediate "wheal and flare" reaction can be followed by a late-phase reaction 5–6 hours later that appears as a poorly defined edema-like reaction and that usually disappears by 24 hours. An allergen extract can be administered either by a prick or puncture or by ID injection.[20]

Puncture skin testing was first described by Lewis and Grant in 1924[21] and modified by Pepys.[22] It involves placing a drop of each test allergen extract or control solutions (histamine and saline) on the skin of the forearm or back and the introduction of allergen into the epidermis by a needle puncture. Importantly, drops are spaced at least 2 cm apart to prevent cross-over bleeding that can produce false-positive reactions or difficulty reading each discrete test site because of overlapping erythema. A variety of single-point (23–26 gauge), multipoint, and bifurcated needles have been used.[20,23] After the prick or puncture, the excess allergen is removed by blotting with tissue paper or gauze approximately 1 minute later. With single devices, separate needles are used to insure no cross-contamination. An immediate reaction (wheal and erythema) is read at 15–20 minutes as it reaches its maximum size. Because of the direct skin irritation with some crude allergen extracts, bleeding can produce false-positive results.

The ID skin test, first reported by Mantoux[24] in 1908, is 1000–30,000 times more analytically sensitive by concentration than the puncture skin test. A 0.02- to 0.05-mL volume of diluted allergen extract or controls (histamine or saline) in a 0.5- to 1.0-mL tuberculin syringe is injected intracutaneously through a 26- to 27-gauge needle. Importantly, the bevel of the needle needs to face up and injection should be no deeper than the superficial layers of the skin. A 0.02-mL injection will initially produce a superficial 2- to 4-mm-diameter bleb. Like the puncture test, the ID skin test is read at 15–20 minutes, when the reaction is maximal. Dilutions of extract >1 : 1000 weight/volume (w/v) are commonly used to minimize false-positive reactions because of irritation and the potential for systemic reactions, which range from 0.02% of 1.4% of patients tested.[20] Subcutaneous administration of the allergen may lead to a false-negative result. The volume of allergen extract that is injected only slightly influences the size of the wheal-and-flare reaction, whereas concentration is the most important determinant of the final ID skin test result. ID testing allows an investigator to perform a skin test titration to quantitatively determine the patient's skin sensitivity. For serial titration, the same volume (*e.g.,* 0.02 mL) of 3–10-fold serial dilutions of allergen extract are injected into different skin sites and the concentration of allergen required to produce a wheal or erythema of a defined mean diameter (*e.g.,* 8-mm wheal) is interpolated.[25] The higher the concentration of allergen required to induce the defined size of wheal or erythema, the less sensitive is the patient to that allergen preparation and/or the lower is the allergenic potency of the extract.

Variables That Influence Skin Test Responses

The quality (composition, potency, heterogeneity) of the allergen extract is the single most important variable that affects skin test performance. Most skin test extracts are nonstandardized, and their potency is reported in biological or weight per volume units.[26] Allergen extracts used in puncture skin testing contain 50% glycerin, which is present to enhance stability. However, the glycerin causes skin irritation and false-positive skin test results if used intradermally without dilution. Other factors that influence the skin test response include the area of the body that is tested (back vs forearm), age of patient (skin wheals increase in size from infancy to adulthood), race (clarity of reading on dark vs light skin pigmentation) and preadministered drugs (*e.g.,* antihistamines, tranquillizers, corticosteroids).

In terms of controls, the saline (negative control) can identify dermatographic patients and trauma-induced reactivity produced by the puncturing device. The histamine positive control (for prick or puncture at 5.43 mmol/L or 1 mg/mL of histamine base) is useful in detecting medication- or disease-induced suppression of the skin test response. It is also used as a quality control reagent to document the reproducibility of technician performance.[27]

Relationship Between Puncture and Intradermal Skin Test Responses

Fig. 95.1 shows the relationship between the ng/mL level of *Dermatophagoides pteronyssinus* (*Dpt,* dust mite) specific IgE antibody in sera from 30 subjects with dust-mite allergy, as measured in serum by an *in vitro* assay, as well as the ID skin test midpoint *Dpt* allergen extract titer required to produce an 8 mm wheal in the same individual. Using the same *Dpt* extract in both tests, a higher degree of skin sensitivity (*i.e.,* lower titer of antigen required to induce an 8-mm wheal) was strongly correlated ($r^2 = 0.77$; $p < 0.001$) with higher serum IgE antibody levels in those with the higher levels of skin sensitivity (<10 ng/mL midpoint). Fig. 95.2 shows the strong correlation between the wheal size that is observed in the same patients with *Dpt* allergy receiving the same dust-mite extract by a single puncture skin test and a midpoint ID skin test titration. Both the puncture and the ID skin test procedures produce a maximal wheal and flare size by 15–20 minutes, which is measured with a millimeter ruler or caliper. The maximal diameter and the midpoint perpendicular diameter are averaged to generate an index. A permanent record of the skin reaction can be made by applying adhesive cellulose tape over the wheal-and-flare skin area, which has previously been outlined with a felt-tip or ballpoint pen. Using a single concentration of allergen, the ID skin test can be graded according to one of several reported systems (Table 95.1).[20,23] Alternatively,

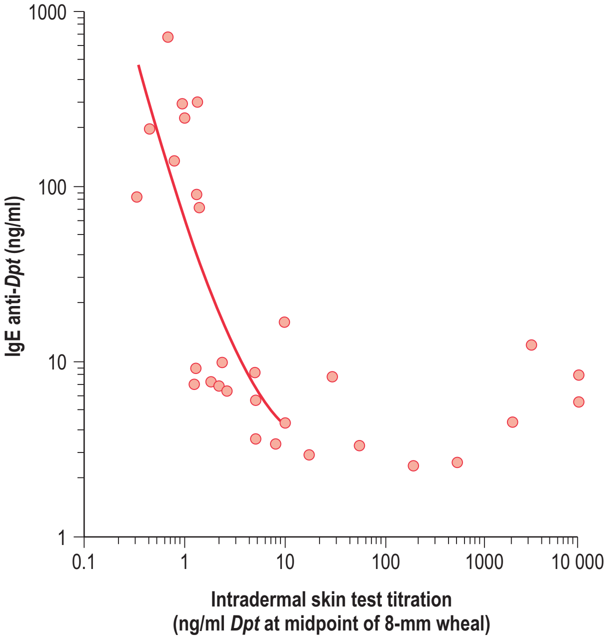

FIG 95.1 Relationship between immunoglobulin E (IgE) anti-*Dermatophagoides pteronyssinus* (*Dpt*) measurements in skin (*x*-axis, intradermal skin test titration; ng/mL of *Dpt* required to produce an 8-mm wheal) and in the serum (*y*-axis, ng/mL of IgE anti-*Dpt* as measured by IgE antibody serology; sensitivity = 2 ng/mL). These results were obtained by testing the skin and serum of 30 individuals with dust-mite allergy and varying degrees of clinical sensitivity by using the same *Dpt* extract in both IgE antibody serology assay and the intradermal (ID) skin test titration study. A lower "titer" of antigen required to induce an 8-mm wheal (*e.g.,* higher degree of skin sensitivity) was strongly correlated ($r = 0.77$; $p < 0.001$) with a higher serum IgE antibody level in individuals with the higher level of skin sensitivity (<10 ng/mL midpoint). Less sensitive patients (titers >10 ng/mL *Dpt*) had lower levels of serum antibody (2–15 ng/mL) that did not relate well with skin sensitivity.

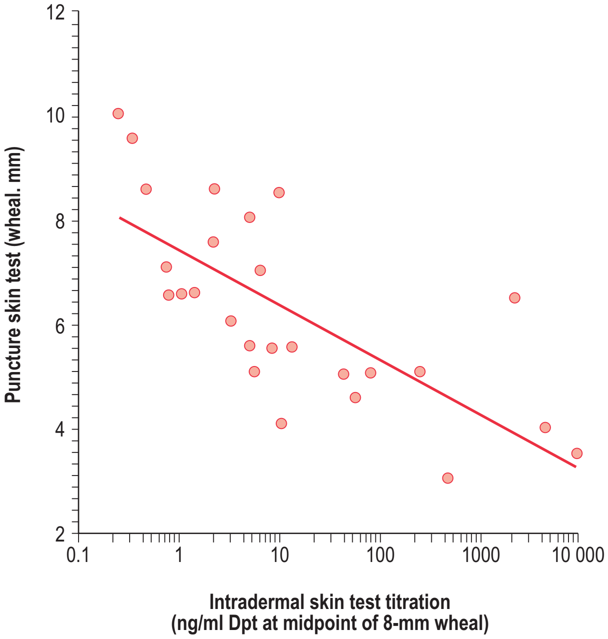

FIG 95.2 The wheal size in millimeters at a single dose of *Dermatophagoides pteronyssinus* (*Dpt*) allergen administered in a puncture skin test compared with the titer or nanogram per milliliter (ng/mL) of the same *Dpt* allergen obtained in an intradermal (ID) skin test titration on the same 26 dust mite-allergic patients to produce an 8-mm wheal. These data indicate that the wheal size obtained with a single dose of allergen by the less labor-intensive puncture skin test is as predictive ($r^2 = 0.72$; $p < 0.001$) of relative patient sensitivity as the more technically complex intradermal skin test titration study, which involves the administration of seven increasing concentrations of the same allergen into different skin sites.

a midpoint titer can be interpolated from a skin test titration, including 3–10-fold serial dilutions of the allergen extract. Some investigators prefer to use the erythema (flare) size rather than the wheal size obtained during titration studies because the slope of the flare's regression line with dose is steeper.[25] The strong relationship between the size of the intradermal erythema and wheal observed with the mean of 304 duplicate skin tests is shown in Fig. 95.3. This relationship is useful to know because the erythema is difficult to assess in many dark-skinned subjects.

Conjunctival, bronchial and nasal provocation tests

Conjunctival, bronchial, and nasal provocation challenges are performed primarily as research procedures to identify a relationship between allergen exposure and a change in the patient's ocular, bronchial, or nasal physiology. Along with puncture skin tests, they are more specific but less sensitive than ID skin tests.[28] Bronchoprovocation studies with methacholine or histamine are the most commonly performed, particularly in the diagnosis of difficult cases of asthma. The bronchoprovocation procedure involves the administration of either methacholine or histamine via a calibrated nebulizer, starting at doses of 0.03–0.1 mg/mL and doubling the concentration up to 10–25 mg/mL. Alternatively, the administration of increasing doses of allergen extracts is performed principally as a research tool to investigate humoral and cellular mechanisms involved in the pathogenesis of allergen-induced airway responses. Pulmonary function is monitored after each dose. A positive response is typically defined as the concentration of agonist that results in a drop in the forced expiratory volume per second (FEV_1) of 20% or more from the baseline. A value >70% of predicted needs to occur to obtain a valid interpretation. More extensive details regarding the methods and interpretation of bronchial challenges are presented elsewhere.[29,30]

Nasal provocation in its simplest form involves the controlled administration of buffer (human serum albumin–saline) or increasing concentrations of allergen into one or both sites of a washed nasal passage in individuals suspected or known to be allergic. The symptoms (*e.g.,* itching, number of sneezes, rhinorrhea, and nasal conjugation) induced and/or degree of mast cell and basophil degranulation markers (*e.g.,* histamine, tryptase, prostaglandin D_2, cysteinyl leukotrienes) and cytokines (interleukin-4 [IL-4], IL-5, IL-10, IL-13) released into nasal lavage fluids after each concentration of allergen indicates the relative level of sensitivity to that allergen. Nasal airway resistance is a less satisfactory endpoint because of high intrinsic variations. Details of the procedures and applications can be found elsewhere.[31]

TABLE 95.1 Grading System for Puncture and Intradermal Skin Testing Using Histamine as a Reference[a]

Grade or Class	Wheel Size (mm)	Erythema Size (mm)
Skin Testing Grading System		
0	No discernible wheal	
1+	≤3 histamine wheal	
2+	>3 histamine and <13 histamine wheal	
3+	= size of histamine wheal ± 1 mm	
4+	>13 histamine wheal and <23 histamine wheal	
5+	>23 histamine wheal	
Alternative Skin Test Grading System for Intradermal Skin Testing Only Involving Interpretation of Wheal and Erythema Responses[†]		
0	<5	<5
+/–	5–10	5–10
1+	5–10	11–20
2+	5–10	21–30
3+	10–15	31–40
4+	>15 with pseudopods	41–50

[a] Prick/puncture histamine (3–10 mg/mL); ID histamine (100 μg/mL).

(Modified from Norman PS. Skin testing. In: Middleton E, Ellis EF, Reed CE, editors. Allergy: principles and practice. 2nd ed. St. Louis: CV Mosby; 1982, with permission from Elsevier.)

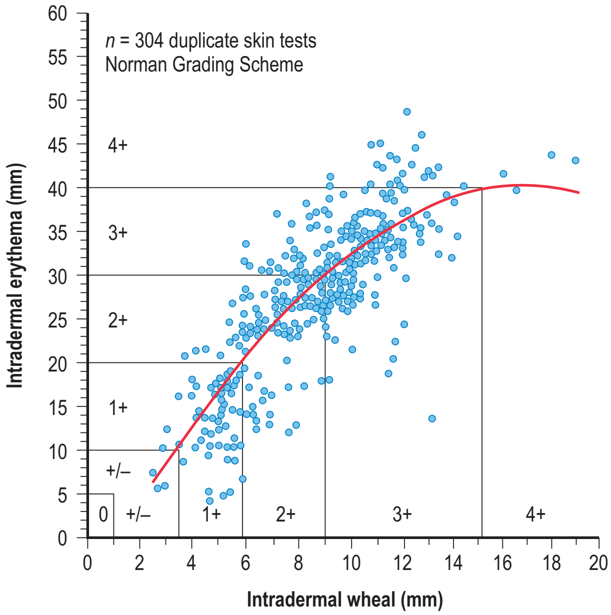

FIG 95.3 Correlation plot of the mean wheal (*x*-axis) and erythema (*y*-axis) in millimeters for the mean of 304 duplicate intradermal skin tests to dust mite (*Dermatophagoides pteronyssinus*) obtained in a population of individuals with sensitivity to dust-mites. The relationship is highly correlated ($r = 0.82$; $p < 0.001$) in grades 0 to 3+, indicating that either can be used to judge the degree of intradermal skin sensitivity. In highly allergic individuals (>35 mm erythema), however, the slope declines dramatically, indicating that wheal size may be more discriminating than erythema.

Oral Food Challenge Tests

Oral food challenges remain the definitive test for food hypersensitivity, since *in vitro* and other *in vivo* diagnostic methods suffer from suboptimal diagnostic specificity.[32] They are performed to establish an accurate diagnosis of food allergy or when skin tests are not possible because of atopic dermatitis or allergic GI disease or to assess the development of tolerance to a food. Passing a direct food challenge ideally permits reintroduction of the food into the patient's diet. Food-induced GI reactions (*e.g.*, nausea, colic, vomiting, and diarrhea) can occur minutes to hours after the consumption of food allergens by a sensitized individual.[33] Commonly eaten foods that contain potent allergens include cow milk (caseins, β-lactoglobulin, α-lactalbumin, lactoferrin, and bovine serum albumin), chicken egg white (ovalbumin, ovomucoid, ovotransferrin), cereal grains (wheat, rye, barley, oats), legumes (peanut, soybean, white bean), and fish and seafood (shrimp, crab, lobster, oyster).

Diagnosis of a food allergy begins with a medical history, which includes an assessment of diet diaries and elimination diets, as necessary. Skin tests and serological tests for IgE antibody to extracted food allergens and open food challenges with fresh and cooked foods can be used to confirm sensitization to suspected foods. No evidence is available to indicate that food-specific IgG or IgG4 antibody levels have any diagnostic value.[34] The double-blind placebo-controlled food challenge (DBPCFC) is considered the definitive diagnostic test for food allergy.[32] The open food challenge has its utility in clinical practice as a first-line challenge procedure as it is easier than DBPCFCs. Moreover, they are especially useful when the probability of a negative challenge is high, since a negative open challenge result can obviate the need for a DBPCFC and it reduces anxiety and thus reduces the risk of bias in infants and young adults. An extensive discussion of open challenges, DBPCFCs, and variables that influence their outcome is presented elsewhere.[32,33]

In 2001, prospectively collected sera from 100 children and adolescents who had been previously evaluated by a skin test and DBPCFC were analyzed in the ImmunoCAP autoanalyzer (Thermo Fisher Scientific/Phadia, Uppsala, Sweden) for food-specific IgE antibody.[35] A diagnostic level of IgE antibody specific for egg (7 kU/L), milk (17 kU/L), peanut (14 kU/L), and fish (20 kU/L) was identified, above which clinical reactivity could be predicted with more than 95% certainty. The study concluded that by measuring the concentration of food-specific IgE antibody with the ImmunoCAP system, a subset of children who were highly likely (>95% probability) to experience a clinical reaction to egg, milk, peanut, or fish could be identified. Importantly, this study and others subsequently have shown that judicious use of quantitative serological measurements for food-specific IgE antibody as measured by ImmunoCAP may be able to eliminate the need for time-consuming DBPCFCs in a significant number of children who are suspected of having food allergy. The relationship between IgE antichicken egg, cow's milk, and peanut as measured in the ImmunoCAP and Immulite (Siemens Healthcare Diagnostics, Tarrytown, NY, USA) has been investigated in an effort to extend published ImmunoCAP predictive values to reported Immulite measurements of IgE antibody to these foods.[36]

IN VITRO TESTING

Clinical immunology laboratories worldwide offer serological tests that are useful in the diagnosis and management of human

KEY CONCEPTS

Immunoglobulin E (IgE) (Reaginic) Antibody Detection

- Allergen-specific IgE can be detected by skin test using a puncture or intradermal administration of allergen or in the serum by laboratory-based immunoassays.
- In general, the intradermal (ID) skin test is more analytically sensitive than a puncture skin test, which is roughly comparable to the best *in vitro* methods for IgE antibody detection in serum.
- ID skin tests are the diagnostic procedure of choice in the workup of patients with suspected *Hymenoptera* venom and drug allergy, while both *in vitro* an *in vivo* assay methods are complementary for evaluating aeroallergen-related disease.
- Serological analyses of IgE antibody–specific for food allergens are often favored over extract-based skin test analyses in part because of more enhanced reagent quality control; however, the double-blind placebo-controlled food challenge (DBPCFC) remains the gold standard for definitive diagnosis of food allergies.
- IgE antibody to allergenic molecules (components) can in some cases (*e.g.,* peanut, hazelnut) provide clarity in terms of the specificity of the patient's sensitization profile (genuine vs cross-reactivity) and relative risk for mild versus serious systemic reactions.

allergic disease. Analytes commonly measured in these laboratories include the total serum IgE, IgE antibodies to hundreds of allergen specificities, *Hymenoptera* venom-specific IgG, the IgE antivenom-inhibition test, and mast cell tryptase. IgG antibody measurements to allergens other than *Hymenoptera* venom have not been shown to be clinically useful.[34] Basophil mediator and activation tests, although rarely offered as clinical tests because of the requirement for fresh blood, are useful investigational methods that are also reviewed in this section.

Total Serum IgE

Of the diagnostic allergy tests that are performed in the clinical immunology laboratory, total serum IgE is currently the only diagnostic allergy analyte regulated under the US Clinical Laboratory Improvement Amendment of 1988 (CLIA-88). Current commercial assays to measure the total level of IgE in serum employ nonisotopic labels, such as enzymes (horseradish peroxidase, alkaline phosphatase, β-galactosidase) or fluorophores, and have been cleared by the US Food and Drug Administration (FDA). The minimum detectable concentration of the commercial total serum IgE assays is between 0.5 and 1 μg/L. The intermethod agreement of the different commercial IgE assays is excellent (*e.g.,* intermethod coefficients of variation [CVs] typically <15%).[13,37] Nonatopic age-adjusted reference intervals for total serum IgE must be used for normative interpretation.[5]

Total IgE Measurements After Therapeutic Anti-IgE Administration

Omalizumab (anti-IgE) is currently used as a fourth therapeutic modality to supplement avoidance, pharmacotherapy, and immunotherapy in the management of persistent asthma and urticaria, and off-label for other IgE-mediated states (*e.g.,* allergic bronchopulmonary aspergillosis, pretreatment of food allergy patients receiving immunotherapy). Since its conception,[38] clinicians have desired to quantify the level of total and "free" (uncomplexed) IgE in anti-IgE treated patients as a rationale for treatment failures or to justify modification of a patient's dosing regimen to maximize treatment success. A systematic evaluation of the impact of therapeutic anti-IgE on the performance of clinically used total IgE assays showed variable interference that resulted in a 1.9–51.9% reduction in accuracy, depending on the assay.[39] Accurate quantitation of the level of uncomplexed or "free" IgE in the serum of treated patients has been more technically difficult. The performance of the existing free IgE assays has been heavily criticized,[40] leading some investigators to a conclusion that there may be no simple and analytically accurate clinical method for quantifying the level of free IgE in the serum of patients who have received omalizumab. This, however, may change with a new anti-IgE therapeutic that has been engineered so it is removed from circulation once it complexes IgE.[41]

Allergen-Specific IgE

Laboratories in the United States that perform clinical diagnostic allergy testing must be federally licensed, use a United States FDA-cleared assay method, and perform successfully in an external diagnostic allergy proficiency survey (*e.g.,* College of American Pathologists [CAP] SE Survey).[13,37] These assays, which have been through rigorous validation, have achieved unsurpassed intraassay precision, interassay reproducibility, and a high degree of quantification.[13] Their basic design can be traced to the first IgE antibody assay, the RAST, reported by Wide et al. in 1967.[12]

Allergen

The most highly variable component of the IgE antibody assay is the allergen-containing reagent. Allergens are mixtures of molecules, typically proteins, glycoproteins, lipoproteins, or protein-conjugate chemicals or drugs that have been solubilized from a defined (usually biological) source, a portion of which can elicit an IgE antibody response in exposed and genetically predisposed individuals. They possess common properties of stability to processing (*e.g.,* heat) and digestion because of multiple cysteine linkages. They tend to be abundant in nature, form aggregates or polymers, commonly interact with lipid structures, and serve to defend their biological source. Cross-tabulation of the protein family (PFAM) database (n = 16 230 proteins families) with the Structural Database of Allergenic Proteins (SDAP) identified 130 PFAMs in the Allergenic Family database of allergenic proteins. Thus importantly, allergens comprise a small fraction of protein families with particular structures and biological functions.[42] The Clinical Laboratory Standards Institute (CLSI) has an established international guidance document that defines the expected performance characteristics of allergenic materials used in immunological assays for human IgE antibodies.[13] It provides a compendium of the genus and species of all the allergen specificities of clinical interest, subdividing them into extract and component allergens and indicating whether they are well-documented or rare. They are categorized on the basis of their sources, into weed pollen, grass pollen, tree pollen, animal dander, mold, house dust-mite fecal material, parasites, insect venoms, occupational allergens, foods, and drugs. Except for drugs, these extracts are complex heterogeneous mixtures that contain both nonallergenic and allergenic proteins. Some allergens share structural similarity or cross-reactive epitopes, and others possess unique IgE antibody-binding determinants. Among the different species of a genus, such as ragweed (*e.g.,* Canyon, Desert, Giant, Short, Silver, Southern, Western), there is extensive allergenic cross-reactivity resulting from structural similarity. Extensive allergenic cross-reactivity has also been documented within other pollen groups, such as the grasses (June, Brome, Timothy, Perennial Rye, Fescue, Orchard, Red Top, Salt, Sweet Vernal, Velvet).

TABLE 95.2 **Principal Allergen Families and Their Associated Biological Functions**

Family	Function	Diagnostic Utility and Clinical Features	Examples
Profilins	Actin-binding proteins involved in the dynamic turnover and restructuring of the actin cytoskeleton. Highly conserved, extremely cross-reactive and ubiquitous proteins in pollen and plant foods	Positive skin test and immunoglobulin E (IgE) responses to (nonrelated) pollen species (often including grasses) and plant food extracts are indicative for IgE cross-reactivity to profilins. After proof of sensitization to one profilin pollen and plant food extracts are of no further use because of their subsequent lack of analytical specificity	Bet v 2 (birch); Phl p 12 (Timothy Grass), Hev b 8 (Natural Rubber Latex), Mal d 4 (apple),
Serum albumins	Highly cross-reactive plasma protein carriers involved in transport of hormones, enzymes, hemin, and fatty acids. Also maintains oncotic pressure	Positive skin test and IgE responses to furred animals indicate IgE cross-reactivity to mammalian serum albumins. Proof of sensitizations to one serum albumin can explain clinical symptoms to rarely or uncooked meat ("cat-pork-syndrome")	Fel d 2 (cat); Can f 3 (dog),
Pathogenesis-related proteins family 10 (PR-10), Bet v 1- homolog	Plant defense proteins; Bet v 1 is a quercetin-3-O-sophoroside-binding molecule (17 kDa); inflammation response proteins	Positive Bet v 1-specific IgE reflects sensitization to fagales tree pollen (*i.e.,* hazel, alder, birch, beech, oak). Thermo and digestion labile Bet v 1-homologs in fruits, legumes, and vegetables. Bet v 1-sensitized individuals can cause predominantly oropharyngeal symptoms after consumption of raw food items (*i.e.,* pip fruits, stone fruits, tree nuts, carrots, soy).	Bet v 1 (birch); Cor a 1 (hazelnut); Mal d 1 (apple); Gly m 4 (soy)
Polcalcin	Cross-reactive, ubiquitous calcium binding proteins in pollen; involved in calcium regulation	Positive skin test and IgE responses to (nonrelated) pollen species are indicative for IgE cross-reactivity to polcalcins. After proof of sensitization to one, polcalcin pollen extracts are of no further use because of their subsequent lack of analytical specificity	Phl p 7 (Timothy Grass); Bet v 4 (birch); Amb a 10 (Short Ragweed)
Nonspecific lipid transfer proteins (nsLTP, PR-14)	Inflammation response proteins; responsible for shuttling phospholipids and other fatty acids between cell membranes	Primary food allergen after sensitization to peach lipid transfer protein (LTP) (possibly through the skin?); predominantly found in the Mediterranean subjects; variable degree of cross-reactivity between the thermally stable LTPs in fruits and vegetables causing frequently oropharyngeal and sometimes systemic symptoms (*i.e.,* exercise-induced)	Pru p 3 (peach); Ara h 9 (peanut); Cor a 8 (hazelnut)
Lipocalins	A highly heterogeneous group of extracellular proteins within various subfamilies involved in transport of small hydrophobic molecules, such as steroids, bilins, retinoids, and lipids	Positive skin test and IgE responses to more than one or many furred animals are indicative for IgE sensitization and subsequent serological cross-reactivity to lipocalins of a certain subfamily. As a consequence animal extracts are of no further use because of their subsequent lack of analytical specificity	Fel d 4, 7 (cat); Can f 1, 2, 4, 6 (dog)
Parvalbumins	Calcium binding proteins; localized in fast-contracting muscles and being involved in calcium signaling	Thermostable and digestion-stable major fish allergen with fairly high, but not complete cross-reactivity and high abundance in almost all fish species. Only limited sequence homology and no cross-reactivity between fish and shellfish Ca^{++}-binding proteins	Gad c 1 (cod); Cra c 4, 6 (shrimp)
Tropomyosins	Integral components of actin filament that play a role in regulating muscle contraction. Also regulate actin filament stability in nonmuscle cells	Thermostable and digestion-stable major shellfish allergen with broad cross-reactivity and high abundance in all shellfish species. IgE sensitization is associated to allergic reactions to various panels of shellfish species	Der p 10 (dust mite); Pen m 1 (shrimp)
Seed storage proteins	Heterodimeric, stable and highly abundant proteins involved in nutrient storage: *e.g.,* 2S albumins, 7/8S globulins (vicilins), 11S globulin (legumins)	Thermostable and digestion-stable important primary food allergens in legumes (peanut, soy), tree nuts (hazelnut), capsule fruits, and seeds with limited cross-reactivity within the subfamilies of different species; primary sensitization starts in early childhood and can persist lifelong; high allergen-specific IgE levels are associated with systemic allergic reactions	Ara h 2 and 1 and 3 (peanut); Cor a 14 and 11 and 9 (hazelnut)

Modified from the I/LA20 Guidance Document from the Clinical Laboratory Standard's Institute. Hamilton RG, Matsson PNJ, Chan S, et al. Analytical performance characteristics, quality assurance and clinical utility of immunological assays for human immunoglobulin E (IgE) antibodies of defined allergen specificities. 3rd ed. I/LA20-A3, International CLSI-Guideline. Wayne, PA: Clinical Laboratory Standards Institute; 2016.

In contrast, other grass pollens, such as those produced by Bermuda Grass, Johnson Grass, and cultivated corn, oat, and wheat, are minimally cross-reactive (allergenically distinct). Variations in the allergenic content of extracted source materials, the extraction process from the raw source material, allergen-reagent manufacturing methods, differential binding to various allergosorbent supports, instability during storage, heterogeneity of internal reference allergen standards, and differences in characterization procedures (antisera, assays) make the production of reproducible allergens for *in vitro* use a challenge.

Cross-reactivity has also been shown at the allergen component level. There are 10 principal allergen families that show structural similarity and extensive cross-reactivity (Table 95.2).[42,43] The most prominent is illustrated by the Pathogenesis-Related (PR)–10 family of allergens, also known as the *Bet v 1 homologues*. These are small (17-kDa) proteins in many plant species that transport steroids and exhibit low stability at high pH and in the presence of digestive enzymes. The first allergen in this family was identified from birch pollen (Bet v 1). Others with high amino acid sequence homology include Cor a 1-hazelnut, Mal d 1-apple, Pru p 1-peach, Gly m 4-soybean, Ara h 8-peanut, Aln g 1-alder, Act d 8-kiwi, Api g 1-celery, and Dau c 1-carrot. Other component based cross-reactivity groups include the profilins, nonspecific lipid transfer proteins tropomyosins, serum albumins, polcalcins, lipocalins, parvalbumins, storage-binding proteins, and carbohydrate cross-reactive determinants (CCDs) (see Table 95.2). Each of these cross-reactive allergen families is extensively discussed in the *Handbook on Molecular Allergology.*[44]

Calibration

The second attribute that varies widely among commercially available IgE antibody assays is calibration algorithm and methodology. There exists no internationally recognized polyclonal human IgE antibody reference preparation. Thus all three autoanalyzers currently in commercial use in the United States have found a heterologous interpolation procedure to be optimal in which allergen-specific IgE antibody response data are interpolated from a total serum IgE calibration curve. This procedure is valid as long as the total IgE calibrators and the patient's allergen-specific IgE antibody levels dilute out in parallel so that parallelism is maintained. The assays report IgE antibody levels in the same units (kUa/L), using internal total IgE calibrators that are cross-verified and traceable to the World Health Organization (WHO) 11/234 IgE international reference preparation.[45] This calibration system allows interpolation of IgE antibody results from a limit of quantitation of 0.1 kUa/L to 100 kUa/L levels of IgE antibody. In terms of quantitation, at least one of the IgE antibody autoanalyzers (ImmunoCAP) has demonstrated equivalence in which 1 kUa/L of chimeric allergen-specific IgE antibody was shown to be equivalent to 1 kU/L (2.4 ng/mL) of total serum IgE.[46]

Single-Plex, Multiallergen, and Multiplex Assays

The autoanalyzers in common clinical use are single-plex (or monoplex) assays in which one analyte (*e.g.,* IgE anti–cat dander) is measured in a single analysis. In contrast, a multiplex antibody assay allows many specificities of a single antibody isotype (*e.g.,* IgE) to be individually detected and semiquantified in a single analysis. These are distinguished from a multiallergen screening assay, which is a form of single-plex analysis that involves the use of a mix of multiple allergens that is immobilized on the same allergosorbent. The purpose of the multiallergen assay is to simultaneously screen a serum for IgE antibody to a concise number (*e.g.,* 10–15) allergens either of the same allergen source type (*e.g.,* foods: chicken egg, cow's milk, peanut, soybean, cod fish) or diverse sources (*e.g.,* respiratory allergens as an aeroallergen mix: pollen from select trees, grasses, weeds, pet epidermals, dust mites, molds).[47] A qualitative result (positive or negative) is generated, and it serves as an inexpensive and efficient single analysis to assess the general atopic status (IgE positivity) of an individual. One multiaeroallergen screening assay is being used to assess the atopic status (genetic predisposition to produce IgE antibody) of research subjects enrolling in clinical studies of asthma.[48] Clinically, the multiaeroallergen screening assay has a high negative predictive power and thus is used to rule out IgE-mediated allergic disease where the suspicion based on the clinical history is weak.

The availability of unlimited quantities of molecular allergens has made it possible to develop multiplex chip based microarrays for diagnostic allergy confirmatory testing. The first microarray for semiquantification of IgE antibody involved a preactivated glass slide or chip on which 94 purified allergens were each immobilized in triplicate microdot arrays.[49] The present day version of this assay is the immune solid phase allergen chip or ISAC (Thermo Fisher Scientific/Phadia, Uppsala, Sweden) in which 40 µL of serum is applied to a chip that has 112 individual allergenic molecules immobilized.[50] IgE anti–cow's milk components as measured in the multiplex ISAC have agreed well with those obtained in a single-plex autoanalyzer using the same allergen specificities.[51] Other groups have tried alternative multiplexing technologies to detect IgE antibodies that have included immobilizing allergen extracts on chips by using Luminex bead–based suspension arrays, employing nanotechnology biosensors, detecting surface plasmon resonance, and using plates equipped to produce electrical pulse generated chemiluminescence.[51,52] When selecting a single-plex or multiplex assay format, one must consider their strengths and weaknesses. Single-plex systems have the advantage of greater analytical sensitivity or a lower limit of quantitation, greater precision and accuracy, more established internal and external quality control, and wider global availability of technology. In contrast, multiplex systems provide increased speed of analysis with reduced turnaround times, conservation of sample volume, greater simplicity, and reduced technical and reagent costs.[52]

The quality of allergen-specific IgE antibody results reported from clinical diagnostic allergy laboratories is not uniformly equivalent. In addition to the variability of results for a given serum between assays from different manufacturers as a result of allergen and calibration variance, the positive thresholds used for the same assay by different laboratories varies (*e.g.,* 0.1, 0.35, and 0.7 kUa/L).[53] For this reason, physicians requesting IgE antibody testing bear some responsibility for determining the quality of the results they receive. In the United States, testing should be performed in a clinical laboratory that is federally licensed for highly complex immunology clinical testing under CLIA-88 (verified by requesting a copy of the federal laboratory license).[54] The requesting physician should inquire about the assay method used, the source of its reagents, and how assays are quality controlled by the laboratory. As part of the formal record, the assay method used in patient analysis should be indicated on the final report.

Competitive IgE Antibody Inhibition Assay

The competitive inhibition format of the IgE antibody assay has been used by researchers, allergen manufacturers, and regulators to determine the relative potency of allergen extracts.[55] One practical research application of the IgE antibody inhibition assay has been as a tool for monitoring the concentration of allergens released into environments (*e.g.,* latex allergen in hospital air[56]; air sampling of airplanes for aerosolized peanut allergen). In the diagnostic allergy laboratory, the competitive IgE antibody inhibition assay has been used analytically to confirm an IgE antibody assay's minimum detectable dose (sensitivity) and nonspecific binding and to document the extent of cross-reactivity by determining the allergen specificity of IgE antibody.[13]

The one clinical application of the IgE antibody inhibition assay has been as an adjunct to define the appropriate therapeutic composition of venoms for patients who have insect-sting allergy with multiple potentially cross-reactive sensitivities and who have elected to receive immunotherapy.[57] Indications for this test include a strong skin reactivity; a high level of serum IgE antibody to yellow jacket venom (YJV) and a weak skin reactivity; or a low level of serum IgE antibody specific for *Polistes* wasp venom (PWV). The structural similarity between *Vespid* and

Polistes wasp phospholipase A1/B (Ves g 1; Pol a 1) and Antigen 5 (Ves g 5; Pol a 5) frequently produces IgE antibody cross-reactivity. Sera from 305 patients with *Hymenoptera* venom allergy with >2 ng/mL of IgE antibody to YJV and PWV were evaluated in the IgE antibody inhibition assay to document its clinical utility. The diagnostic question for these patients is whether PWV should be included in the venom immunotherapy together with yellow jacket or mixed vespid venom. Using this procedure, the venom-specific IgE antibody inhibition assay identified one-third (36.4%) of subjects with a primary YJV sensitivity who were candidates for exclusion of PWV from their immunotherapy regimen because their IgE anti-PWV was >95% cross-inhibitable with soluble YJV.[57]

More recently, molecular venom allergens may be particularly useful in clarifying whether patients with venom allergies with IgE antibody positivity for two or more distinct venoms (YJV, HBV, and/or PWV) reflects true multiple venom sensitization or whether the observed multiple positivity results from either clinically irrelevant cross-reactive carbohydrate-specific IgE antibodies or common protein epitopes of homologous venom antigens.[58] The important carbohydrate cross-reactive determinants (CCD) in insect venoms involves an α1,3-linked fucose residue that is attached to the innermost N-acetylglucosamine carbohydrate on venom proteins.[59] For YJV and HBV, the known cross-reactive proteins include hyaluronidase (Api m 2, Ves v 2), dipeptidyl peptidase (Api m 5, Ves v 3), and vitellogenin (Api m 12, Ves v 6). IgE antibody cross-reactivity between YJV and PWV is independent of CCD and can occur as a result of common epitopes on homologous antigens: Antigen 5 (Ves v 5, Pol d 5) and phospholipase A 1 (Ves v 1 and Pol d 1).[60] Specific IgE antibody measurements against rVes v 5 and rPol d 5 alone were able to aid in differentiating sensitivity against *Vespula* and *Polistes* venoms in some patients. However, Savi et al.[61] concluded that the venom competitive inhibition analysis remains the optimal serological test at present for differentiating between true and cross-reactivity–related dual *Vespula* and *Polistes* venom sensitization. Moreover, when rPol d 1 becomes available for testing in parallel with currently available Ves v 1, Ves v 5, and Pol d 5, the effectiveness of molecular allergen based differentiation of dual *Vespula* and *Polistes* venom sensitization will need to be reassessed.

CLINICAL PEARLS

*Clinical Utility of Immunoglobulin E (IgE) Anti-***Hymenoptera** *Venom Inhibition Test*

- Useful in identifying venom cross-reactive IgE antibodies and selecting appropriate venoms for immunotherapy.
- One-third of venom-allergic patients with concomitant yellow jacket venom (YJV) and *Polistes* wasp venom (PWV) sensitivity can be treated with YJV alone or mixed vespid venoms, owing to >95% cross-reactive IgE anti-PWV with soluble YJV.

Allergen-Specific IgG

Allergen immunotherapy is known to enhance the production of specific IgG "blocking" antibodies.[62,63] Quantitative measurements of allergen-specific total IgG or IgG subclass antibodies in studies of allergic rhinitis have not generally correlated with the control of clinical symptoms in individual patients. However, clinically successful immunotherapy is almost always accompanied by high serum levels of allergen-specific IgG (typically IgG1 and IgG4) blocking antibodies.[63] Interestingly, despite a decrease to preimmunotherapy baseline levels after 2 years of immunotherapy discontinuation, overall functional inhibitory activity, as measured by an IgE-dependent facilitated allergen binding assay, appears to be maintained.[63] For patients *with Hymenoptera* venom allergy, specific IgG antibody measurements have been used as an indicator of effective immunotherapy. Quantitative venom-specific IgG antibody levels may be useful in individualizing the dose and frequency of injections while maximizing the protective effects. However, their clinical utility may be restricted to the first 4 years of venom immunotherapy.[64] In contrast, the presence or levels of IgG antibodies specific for food antigens have shown no correlation with the results of positive DBPCFCs, and they are not indicated in the diagnostic workup of a patient with suspected food allergy.[34]

CLINICAL PEARLS

Immunoglobulin G (IgG) Antibody Measurements

- Clinically successful aeroallergen immunotherapy is almost always accompanied by high serum levels of allergen-specific IgG (predominantly of the IgG1 and IgG4 subclasses).
- Quantitative venom-specific IgG antibody levels can be of value in individualizing venom doses and frequencies for patients on venom immunotherapy for up to 4 years.
- Food-specific IgG and IgG4 assay results do not correlate with the results of double-blind placebo-controlled food challenges and are not clinically indicated.

Mast-Cell Tryptase

Mast cells have been identified in skin, respiratory, and digestive tract connective tissues and distinguished on the basis of the neutral proteases present in their secretory granules. One group contains only tryptase, whereas the other contains both tryptase and chymase.[65] Mast-cell tryptase (MW 134 kDa) is a serine esterase with four subunits, each having an enzymatically active site. A resting mast cell contains 10–35 picograms (pg) of tryptase that is stored attached to heparin. When dissociated from heparin, it rapidly degrades into its monomers and loses enzymatic activity. As basophils have ~500-fold less tryptase compared with mast cells, elevated tryptase levels in serum are considered a relatively specific indicator of mast-cell involvement in a clinical reaction. Unstimulated tissue mast cells continually secrete immature protryptase into the tissue, and it diffuses into the circulation to provide a measure of total mast-cell number. α-Protryptase and β-protryptase represent the bulk of the immature tryptase in nonanaphylactic sera. α-Protryptase remains enzymatically inactive, whereas some of β-protryptase is autoprocessed from the proform within the mast cell into the mature enzyme by a dipeptidase where it is stored in granules.[66] Only upon activation of mast cells are both the pro and mature forms of tryptase secreted in parallel with prestored histamine and newly generated vasoactive mediators. Total tryptase in serum from healthy humans ranges from 1 to 11.4 μg/L (average 3–5 μg/L). Mature tryptase is normally undetectable (<1 μg/L) in serum from healthy individuals who have no history of anaphylaxis during the preceding hours. A noncompetitive two-site fluorescent enzyme immunoassay (Phadia, ImmunoCAP) is available to measure total tryptase in serum. Elevated levels of total tryptase (>11.4 μg/L) can be detected in serum 1–4 hours after the onset of systemic anaphylaxis with hypotension. Baseline levels of >20 μg/L are detected in most individuals with systemic mastocytosis.[66]

Recommended serum collection times for tryptase quantification range from 30 minutes to 4 hours after the onset of an acute event. Because serological tests for mature tryptase are not widely available, it is important to compare an acute event total tryptase level (within 4 hours) with a baseline total tryptase 24 hours after all signs and symptoms of the event have subsided.[66] Postmortem specimens are often difficult to analyze for tryptase because of high viscosity related to gross hemolysis. However, reported mature tryptase levels in postmortem cases of fatal anaphylaxis have ranged from 12 to 150 μg/L in all nine fatalities caused by *Hymenoptera* venom and in six of eight food-induced fatalities.[67] The frequency of a severe reaction to venom from a *Hymenoptera* sting increases significantly with higher serum baseline total tryptase concentrations.[68,69] The clinical indications for and diagnostic value of tryptase as a marker of anaphylaxis and mastocytosis are reviewed elsewhere.[68]

Basophil Mediator Release Assays

There are a number of diagnostic assays for sensitization that use the basophil as the indicator modality. Some assays monitor the magnitude of mediator release from basophils, and others assess the degree of cell surface marker expression following exposure to allergen.

Histamine Release Assay

The potent vasoactive mediator histamine is stored in cytoplasmic granules of basophilic leukocytes and mast cells. It is released along with other mediators of inflammation in response to both immunological and nonimmunological stimuli.[70] The basophil histamine release (BHR) assay has been particularly useful as a quantitative assay of allergen potency and as an *in vitro* model for the study of triggering mechanisms of mediator release from basophils. In its most basic form, peripheral blood leukocytes are isolated from a donor and incubated with varying concentrations (*e.g.*, 3–10-fold dilutions) of allergen extract or antihuman IgE as a positive control. Histamine release is complete within 30 minutes, and then histamine in the supernatant is measured by enzymatic, radiometric, or spectrophotofluorometric techniques.[71] Details of the BHR assay are given elsewhere.[70,72]

Patient sensitivity for a given allergen can be determined with a positive BHR test. The results are highly correlated with those determined by skin testing[71] and bronchoprovocation.[73] Although the BHR test has been almost exclusively used in research laboratories because of its expense, time-consuming nature, and the need for fresh blood (<24 hours old), it can be successfully applied to the clinical diagnosis of allergic disease in selected cases. Its results parallel those of other IgE antibody tests. BHR has also been a useful tool for clarifying discrepancies between skin test and serological IgE antibody test results.

Leukotriene C4 (LTC4) Release Assay

An assay method for measuring LTC4 released from allergen-activated basophils has been reported as the cellular antigen stimulation test (CAST)–enzyme-linked immunosorbent assay (ELISA).[74] The LTC4 assay is designed for use with either whole blood preparations or washed leukocytes. Using dust-mite, food, *Hymenoptera* venoms[75] and drugs as challenge allergens, the observed diagnostic sensitivity of the CAST compared with the combination of a clinical history and skin test ranged from 18% with aspirin and 50–85% for selected food allergens.[76] The reported diagnostic specificity of the CAST in the same studies ranged from 67% to 100%. These data indicate that the CAST assay is not sufficiently sensitive for effective clinical use in the diagnosis of IgE-mediated sensitivities to β-lactam or nonsteroidal antiinflammatory drugs (NSAIDs). Its utility in the diagnosis of sensitization to other allergen specificities appears more promising, but further documentation involving clinical studies is required.

Utility of Mediator Release Assays as Diagnostic Tests

Despite their unquestioned value as research methods, the basophil histamine and LTC4 release assays are rarely used clinically in the routine diagnosis of human allergic disease, and it is unlikely that this trend will change in the foreseeable future.

Flow Cytometry Basophil Activation Assays

In the late 1990s, basophils were shown to upregulate the expression of a number of surface proteins (*e.g.*, CD45, CD63, CD69, and CD203c) when activated by allergen.[76-78] CD63 is a member of the transmembrane-4 superfamily that is expressed on basophils, mast cells, macrophages, and platelets.[76,77] In resting basophils from individuals without atopia and allergies, CD63 is attached to intracytoplasmic granules. Activated IgE-sensitized basophils express a high density of CD63 on their surface. By quantifying ~500 basophils with gated flow cytometry, the percentage of activated basophils can be identified, after correcting for spontaneous CD63 expression. A variety of criteria are used to identify an allergen-induced positive response, such as a stimulation index (allergen-induced/basal ratio) >2. One confounding variable in this analysis is the adherence of CD63-expressing platelets in basophil preparations that can sometimes generate false-positive results.

The flow assay stimulation test (FAST), which is also referred to as the basophil activation test (BAT) or BasoTest, uses CD63 as a marker for activation. Its performance was evaluated by using minor determinant mixture, benzyl penicilloyl polylysine, penicillin, ampicillin, amoxicillin, and cephalosporin as stimulating antigens.[78,83] Subjects (n = 58) with a history of immediate-type reactions to β-lactam antibiotics or nonallergic controls (n = 30) were evaluated in the CD63 FAST/BAT and Phadia ImmunoCAP system for drug-specific IgE levels. Relative to the clinical history, the CD63 FAST/BAT displayed a diagnostic sensitivity and specificity of 50% and 93%, respectively. Diagnostic sensitivity was marginally increased to 66% by simultaneously using the drug-specific IgE antibody serology result. The study concluded that the CD63 basophil activation test could be helpful in supporting the diagnosis of IgE-mediated allergy to β-lactam drugs when used in conjunction with an additional diagnostic test, such as IgE antibody serology.[79]

CD203c (also known as *neural cell surface differentiation antigen, E-NIPP3 PD-1β, 97A6, B10,* and *gp130rb13–6*) is a member of the ectonucleotide pyrophosphate phosphodiesterase (E-NPP) family.[80] It is expressed only on IgE-bearing basophils, mast cells, and their progenitors and is upregulated after activation of IgE-sensitized basophils with allergen or anti-IgE in a manner similar to CD63. The CD203c-based flow assay is performed in a manner analogous to the CD63-based assay. Its advantage over CD63 is its restricted expression on basophils in peripheral blood, which minimizes concern about the adherence of platelets that may produce false-positive CD63 results. Additionally, there is no need for the use of an additional fluorescent anti-IgE reagent to gate the basophils. Basophil activation as determined by CD203c expression was studied in patients with allergy to *Hymenoptera* venom and healthy controls in which their basophils were activated with anti-IgE or bee/*Vespid* venoms.[81] Fifteen minutes after stimulation, basophils from 15 wasp-sensitized patients upregulated CD203c expression from 4.2-fold to 13.5-fold. Moreover, basophils from six patients with honeybee venom allergy upregulated CD203c by a mean of 8.3-fold. The study concluded that the CD203c-based flow assay could confirm the presence of venom-specific IgE antibody on basophils in 20 of 22 of patients (91%) with a clinical history of and skin test positivity to venom allergy. One false-positive result was observed among 13 healthy controls with a negative result on the skin test.

Diagnostic Utility of Basophil Activation Flow Cytometric Assays

The utility of basophil activation flow cytometric assays is limited by a number of technical concerns.[79,82] First, endotoxin-free whole blood must be received within 24 hours by the laboratory, where it can processed by skilled technologists. Second, the blood is preincubated with stimulation buffer often containing IL-3, which primes basophils. It is unclear what effect IL-3 has on altering mediator release or CD63/CD203c upregulation, and thus false-positive mediator release and/or biomarker surface expression are potential concerns. Third, varying concentrations of crude allergen extract or recombinant allergen or anti-IgE are incubated with the cell preparation. Unfortunately, crude extracts lack potency estimates and can often be cytotoxic. Thus each stimulating allergen needs to be prequalified with basophils from well-characterized patients before use. Fourth, criteria for defining positive assay results vary among the laboratories performing the test, and stimulating allergen preparations from even the same manufacturer can have variable potency. Fifth, there is a concern about false-positive results related to platelet adherence on basophils in the CD63 based BAT assay. Possibly most important, when the performance characteristics were directly compared in clinical studies to puncture skin test results, the diagnostic sensitivity and specificity of the flow-cytometric analysis of *in vitro* allergen-activated basophils was less than optimal. For these reasons, cell-based cytometric methods will most likely remain useful research techniques for the investigation of allergic disease, but they will have limited application to clinical diagnosis.

ON THE HORIZON

New trends in laboratory methodology for the assessment of human allergic diseases include the following:

- Although there is a transition from the use of crude allergen extracts to allergenic components in immunoglobulin E (IgE) antibody serological assays, extracts will remain the principal allergen reagent source for the foreseeable future because of their comprehensive nature.
- Multiplexing platforms are being increasingly developed to allow rapid simultaneous detection of IgE antibodies to many allergenic components using microliter quantities of serum; however, due to their semiquantitative nature, fixed panel of specificities, and lower analytical sensitivity, single-plex assays will remain the most cost-effective and widely used assay format for the foreseeable future.
- Qualitative "point of care" IgE antibody assays to rapidly assess sensitization to aeroallergens during the patient's visit will be slow to be adopted because of their limited/fixed allergen menus, lower diagnostic sensitivity, and concern about potential patient misinterpretation of results.

MULTIPLE-CHOICE QUESTIONS

1. In the diagnostic workup of a patient with a clinical history of a systemic anaphylactic reaction involving hypotension following a sting from a *Hymenoptera*, total and mature mast cell tryptase were requested to confirm mast cell involvement. What is the correct time to collect a whole blood specimen for a total and mature tryptase analysis?
   A. Immediately following reaction onset
   B. 0.5–4 hours following the reaction onset
   C. 4–12 hours following the reaction onset
   D. 15–24 hours following the reaction onset
   E. 24 hours following reaction onset

2. In the workup of a patient for a food allergy, several procedures are typically involved. Which is the optimal sequence of events for these procedures?
   A. Oral provocation tests are first performed, followed by the clinical history and then *in vivo* and/or *in vitro* tests for immunoglobulin E (IgE) antibody (sensitization).
   B. *In vitro* tests for sensitization are performed first, followed by collection of a clinical history and then oral provocation testing.
   C. Clinical history, followed by either *in vivo* or *in vitro* tests for sensitization and then an oral provocation test, if needed.
   D. Skin testing is performed first, followed by serology blood testing and then collection of the patient's clinical history; oral food challenge is considered the last resort.
   E. Performing a multiplex chip–based IgE antibody assay for identifying sensitization before collecting a clinical history from the patient.

3. Allergenic components are increasingly available to dissect the patient's IgE antibody sensitization profile. Exposure to which of the following principal allergen families poses the most serious risk for the induction of a systemic allergic reaction in an individual with peanut allergy?
   A. Lipocalins, which bind steroids, retinoids, and lipids
   B. Polcalcin, which is associated with calcium regulation
   C. Storage proteins (2S albumins, 7S globulins [vicilins], and 11S globulins [legumins]), which are involved in nutrient management
   D. Pathogenesis related protein 10 family (PR10), which are plant-related defense proteins
   E. Tropomyosins, which are integral components of actin filaments

Molecular Methods

John W. Belmont

Molecular analysis of genes and genomes can be central to arriving at a precision diagnosis. This chapter reviews the basic principles that underlie clinical molecular genetic testing, assesses representative standard methods that are widely employed, describes new DNA sequencing methods that are being rapidly introduced into clinical diagnostic laboratories, and suggests a multidisciplinary approach for implementation in immunological disorders.

BASIC PRINCIPLES

Genome Structure and Gene Expression

KEY CONCEPTS

Human Genomics

- The human genome encompasses approximately 20 000 protein-coding genes, but each cell expresses only a subset of those genes.
- Genetic and physical maps of the genome are essential to molecular diagnosis of immune system diseases.
- Genetic maps depend on the coinheritance of DNA segments—linkage—to associate DNA variants with disease.
- Physical maps of the genome describe the exact gene locations on a chromosome. The genome DNA sequence is the finest scale physical map of the genome.

The human genome is thought to have about 20 000 protein-coding genes distributed on 23 pairs of chromosomes (http://www.ncbi.nlm.nih.gov/entrez/). The total length of one copy of the genome is ≈3×10^9 nucleotide bases. The protein-coding segments (exons) are split by noncoding DNA sequences (introns). The aggregate protein coding sequences, referred to as the "exome," account for about 1–1.5% of the genome. Some of the remaining DNA contains regulatory elements that direct the expression of genes, control chromatin conformation, encode regulatory RNAs, act as origins for DNA replication, and participate in three-dimensional (3D) looping to produce the large-scale chromosome structure. About 40% of the total DNA is accounted for by families of repeated sequences. These repeat elements are generally silent, but they may be involved in some types of gene regulation and can become involved in mutational mechanisms of deletion, duplication, and insertion. Each cell expresses only a subset of the entire gene repertoire. "Housekeeping" genes are expressed in almost all tissues and cell types, where they perform basic metabolic and structural functions. Other genes are under very specific control, and their expression is restricted to one or a few cell types. Differential gene expression specifies the unique functions of cells (*e.g.,* immunoglobulin [Ig] in B cells, and T-cell receptor [TCR] in T cells). Genes that coordinate the expression of groups of tissue-specific genes primarily encode transcription factors that regulate the rate of messenger RNA (mRNA) transcription on their target genes. A few of these apparently act as "master" genes during particular developmental processes or in specific cell lineages. Some of these master genes (*e.g., PAX5*), may be involved in leukemias and lymphomas. So far, immunodeficiency genes appear to be in the category of genes that involve either innate or adaptive immunity controlling cell growth, differentiation, effector functions, or apoptosis.[1,2]

Polymorphic Variation and Linkage

A genetic map relates one gene to another based on how often they are inherited together. Within a specific region of the DNA, the maternal and paternal copies of the genome may be nonidentical, and the variants are called *alleles.* Protein and nucleotide differences are called *polymorphisms* when they are frequent enough to be found in 1–5% of the general population. Variations in single nucleotides occur in ≈1/100 bases when whole-genome sequencing is used to survey individuals.[3] Polymorphisms arise over time in a group of individuals because of mutations in the DNA (Fig. 96.1). Some polymorphisms involve simple sequence repeats so that there is variation in the number of repeat units. These are called *short tandem repeats* (STRs) and are widely used in forensic identification. In contrast to STRs, the most common polymorphisms involve a change in a single nucleotide position. Large databases of single nucleotide polymorphisms (SNPs, pronounced "snips") have been accumulated (http://www.ncbi.nlm.nih.gov/SNP/). It is thought that there could be >30×10^6 SNPs with minor allele frequency >5% available across the human genome. Many SNPs are found in noncoding DNA, and these have been shown to play a significant, albeit incompletely understood, role in common human diseases.

The composition of alleles within genetic loci in an individual is called the *genotype.* The individual's genotype interacts with the environment throughout life to create the *phenotype.* Some components of the phenotype, such as body weight, are simple to measure, whereas other clinically important phenotypes are based on complex laboratory evaluation (*e.g.,* in T-cell proliferation). A key distinction is drawn between discrete traits (normal vs abnormal) and quantitative traits (continuous range of values). Polymorphisms account for some of the variation observed at the phenotype level between healthy individuals or between populations, and the cumulative percentage of the variation explained by genetic variation is called *heritability.* In monogenic diseases (also called *mendelian diseases*), the presence of mutation(s) is usually considered necessary and sufficient to cause disease. The landscape of genetic variation in each individual

FIG 96.1 Classes of DNA Variation Important for Genetic Testing and Human Genetic Diseases. DNA variations can be either benign or pathogenic, depending on whether they affect the underlying functions of a genetic locus and the encoded proteins. An international standard nomenclature is used to describe changes in the DNA. Structural variants have been found to be a common cause of human genetic disorders.

includes a continuum of gene effects ranging from weak (common SNPs detected in disease association studies) to strongly determinative (rare mutations detected in single gene disorders).

Genes can be mapped in relation to one another by a *linkage* map. Genes that are physically close can be shown to be predominantly coinherited. Linkage mapping played a large role in the identification of the X-linked immunodeficiency genes (Chapters 22, 33–36). Beyond small families and at the population level, the correlation of alleles among markers that are very close to each other in the genome is called *linkage disequilibrium* (LD). LD occurs because the mutation that creates a polymorphism occurs on a single chromosome with its whole complement of unique variants. This initial arrangement of alleles, however, is broken up by recombination over time. Hence, only markers that are relatively close to each other continue to have significant LD. A large international project (HapMap) created a dense map of SNP markers allowing a comprehensive view of LD in several reference populations.[4] This information has been efficiently exploited in genetic epidemiology projects called *genome-wide association studies* (GWAS; www.gwascentral.org), which have characterized several thousand common variants that contribute to many common immunological diseases, such as diabetes, rheumatoid arthritis (RA), and systemic lupus erythematosus (SLE).

The advent of projects that assess whole exomes and genomes in normal and disease populations, such as the 1000 Genomes Project (www.1000genomes.org/), has focused much more attention on rare genetic variation, particularly alleles with frequency of 0.01–1.0%. It is also apparent that the extent of individual genetic variation was underestimated from previous data and that each individual bears about 3.5 million simple nucleotide variants and about 1000 structural variants, many of which are unique to that person. Even given some technical reservations, the enormous extent of private variation has been clearly established.

Linkage and LD mapping have been much less useful for the identification of autosomal recessive genes responsible for many primary immunodeficiencies (PIDs) because the diseases are rare in the population and average families are not large enough to narrowly localize the causative genes. Whole-genome and exome sequencing technologies are being used to solve a great fraction of remaining single-gene disorders, including PIDs.[5,6] The biggest difficulty with these conditions is that similar clinical diseases can be caused by mutation in more than one gene locus (*locus heterogeneity*). Another challenge is that it may be difficult to ascertain multiple extremely rare families with mutations in the same gene. Criteria for rare disease gene identification have been proposed and have helped harmonize standards for future genome interpretation.[7] Successful identification of pathogenic variants, even those unique to single pedigrees, can be accomplished by combining DNA sequencing with complimentary functional technologies.

Physical Maps and DNA Copy Number Variation

Physical maps are different from the genetic map in that they describe how genes are arranged in the DNA on a scale as large as a whole chromosome and as fine as a single nucleotide. At the coarsest level of the physical map, genes are placed in chromosome segments corresponding to the Giemsa-stain banding pattern of metaphase chromosomes. A way to localize genes is to hybridize region-specific DNA probes directly to a chromosome spread. The technique, called *fluorescence in situ hybridization* (FISH), allows the detection of signals from the chromosome spread to directly localize genes.[8] FISH is used for cytogenetic examination of tumors, leukemias, and lymphomas but now has been largely replaced by array *comparative genome hybridization* (CGH), which examines many hundreds of thousands of positions using oligonucleotide probes.[9] High-density oligonucleotide arrays allow for both standardization of reagents between diagnostic laboratories and extensive customization for particular disease applications. These methods are detailed below. Pathogenic *copy number variants* (CNVs) are a major cause of birth defects and intellectual disability,[10] so evaluation for CNVs should be considered a first-line test for any infant or child with a complex presentation of immune deficiency. In DiGeorge syndrome (DGS), the characteristic deletion of chromosome 22q11 can be detected by microarray. FISH should not be used because microarray not only provides high-resolution determination of the deletion size but also leaves open the possibility of detecting other unsuspected DNA copy number abnormalities.

Mutation and Pathogenic Variants

KEY CONCEPTS

Mutation

- Mutation can occur by deletion, insertion, or duplication of short or long DNA segments.
- Single-base mutations can be caused by replication errors or by chemical deamination of methylcytosine.
- Single-base mutations can affect protein coding sequence, regulatory sequences, or the RNA splice signals within a gene.
- The parental origin of mutations (maternal or paternal) affects those mutational mechanisms most likely responsible.
- A disease can be caused by mutations in several alternative genes (locus heterogeneity).
- Most primary immunodeficiencies occur because of different kinds of mutations in particular genes (allelic heterogeneity).

DNA variants can involve single nucleotide substitutions, small or large deletions, insertions, inversions, duplications, or repeat expansions.[11] Some variants have no measurable or functionally significant phenotypic effect. They become one of the huge pool of neutral polymorphisms in the genome. Single-base substitutions in a triplet amino acid codon often disturb the normal function of proteins. These are described as *missense* (*i.e.,* causing an amino acid substitution) or *nonsense* (*i.e.,* terminating translation) mutations. Mutations affecting regulatory or splice signal sequences in RNA can also be deleterious. The primary mechanisms of mutation are misincorporation of nucleotides and faulty repair of chemically damaged nucleotides (*e.g.,* 8-oxodG) during DNA replication by DNA polymerases. Another important mechanism underlying single base or "point" mutations occurs at CpG dinucleotides. The cytosine is often methylated, and chemical deamination of the methylated cytosine gives the base thymidine. At the next round of replication the CG may be changed to TG or CA, depending on which DNA strand was altered. Small insertion and deletion (*indel*) mutations are also very common. Indels occurring in protein coding sequence are usually deleterious, as they can cause frameshifts (changing the reading frame, leading to translation termination within a few codons) and account for almost 25% of known human disease causing mutations.[12] They result from strand slippage in repetitive sequences and misaligned intermediates during DNA synthesis. An entirely different mechanism for mutation is expansion of short repeat segments (most often trinucleotides).[13] So far, no disorder that affects the immune system has been associated with this mechanism.

Heritable mutations can arise in either the male or the female germline, but the gender-related frequency is influenced by the mutational mechanism. Chromosomal nondisjunction, for example, occurs predominantly during female meiosis and has a strong maternal age effect.[14,15] The fact that spermatogonial proliferation occurs throughout life and involves many more cell replications than oogenesis increases the single base mutation frequency in the paternal germline.[16,17] Clinicians must cope with both locus and allele heterogeneity. *Locus heterogeneity* means that the same or a similar phenotype results from mutation in one of several different genes. For example, severe combined immunodeficiency (SCID) can result from mutation in the adenosine deaminase, interleukin-2 (IL-2) receptor γ-chain genes, *JAK3,* and so on. *Allelic heterogeneity* means that the disease is caused by different mutations in the same gene. In X-linked disorders, allelic heterogeneity is typically high because affected individuals have reduced reproduction (negative evolutionary selection), and most mutations are lost in the population after a few generations. At autosomal loci some mutations have reached appreciable frequency as a result of demographic processes (*e.g., founder effect*). In the heterozygous state, recessive mutations can be weakly deleterious, neutral, or actually confer a small advantage. Because the mutant alleles are common, it is possible to test affected individuals and potential carriers directly for those mutations. This is the basis for population screening for carrier status in cystic fibrosis. However, none of the immune deficiencies results from common mutations that would permit efficient screening. In the autosomal recessive immune deficiencies, most patients have two different, very rare mutations (*compound heterozygosity*) at the disease locus. If there is known parental consanguinity or the family comes from an isolated population, the affected individual may be homozygous for a rare mutation.

X-Chromosome Inactivation

Disturbances in the pattern of X inactivation are interesting phenomena in women who are carriers of X-linked disorders, including several immune deficiencies.[18] Measurement of X-chromosome activity in the blood cells of normal women shows that, on average, the contribution of maternal and paternal X chromosomes is approximately 50:50. Extreme skewing of X inactivation often results from abnormal proliferation of blood cells. X-inactivation analysis can be used to demonstrate clonal growth of premalignant (*e.g.,* myelodysplasia) and malignant cells. In a female carrying mutations at the X-linked severe combined immune deficiency (*XSCID*; OMIM 300400), agammaglobulinemia (*XLA*; OMIM 300300), or Wiskott-Aldrich syndrome (*WAS*; OMIM 301000) loci, cell competition and compensation mechanisms lead to a reduced contribution of cells expressing the mutant allele among affected cells. In XLA, the B-cell lineage shows selective use of the nonmutant active X chromosome. In XSCID, skewing of X inactivation is observed in B cells, T cells, and natural killer (NK) cells. In WAS, some degree of skewing of X inactivation results from defective hematopoietic stem cell (HSC) activity. Historically, skewed X inactivation was very helpful in linkage mapping of these conditions. As a clinical test, X inactivation now has reduced importance compared with direct mutation analyses.

DESCRIPTION AND PRINCIPLES OF DNA DIAGNOSTIC TECHNIQUES

The overriding theme of all DNA diagnostic techniques is the detection of variants in the DNA molecule that are associated with disease. This has historically involved a targeted search in one or a few specific genes or regions, but the field is evolving rapidly toward techniques that allow for simultaneous survey of the entire genome. DNA copy number analysis and DNA sequencing have come to dominate individual genetic diagnostic methods. Bioinformatics is a necessary diagnostic laboratory discipline that must be coupled to these methods, particularly when the whole genome is surveyed.

Detection of Disease-Causing Copy Number Variants: FISH and Microarrays

Many genetic diseases are caused by deletions or duplications in human DNA. These conditions typically have copy number abnormalities ranging from 500 kilobases (Kb) to 5 megabases (Mb) and are sometimes referred to as “genomic disorders.” The most common genomic disorder with a clinically important effect on the immune system is 22q11 deletion syndrome. This disorder affects about 1 per 4000 live-born infants and accounts for about 90% of DGS cases. The karyotype, in which a metaphase chromosome spread was stained and visualized under the microscope, was for many decades the only clinically useful test for the detection of copy number changes. The karyotype offered a genome-wide view, but at a very low resolution: alterations smaller than 5 Mb, including those that typically cause DGS, were not routinely detected. Two methods, described below, have replaced conventional karyotypes for routine genetic diagnosis. Whole-genome sequencing (WGS) combined with advanced bioinformatics methods promises to transform evaluation of CNVs yet again. In principle, the data collected in WGS can be used to resolve all CNVs regardless of length, thus capturing all forms of structural DNA variation from the smallest to gross abnormalities in chromosomes.

Fluorescence *in situ* Hybridization

FISH has been an important technology for detecting both constitutional and somatic abnormalities in chromosomes.[19] In its simplest form, a cloned gene segment (referred to as a *probe*) is labeled (Fig. 96.2) and allowed to hybridize to a preparation of early metaphase (condensed) chromosomes. The labeled probe hybridizes specifically to a locus and is then detected with secondary antibodies and high-sensitivity immunofluorescence techniques. The targeted locus appears as two pairs of dots corresponding to the sister chromatids from the two chromosomal homologues. Cells that are in interphase (when the DNA is largely unfolded in the nucleus) can also be probed. In the interphase cell, two single signals are observed corresponding to the two chromosomes. With the introduction of microarray-based methods for genome-wide copy number analysis, the practical application of FISH has been narrowed but does have a continuing role in defining balanced translocations and in cancer cytogenetics.

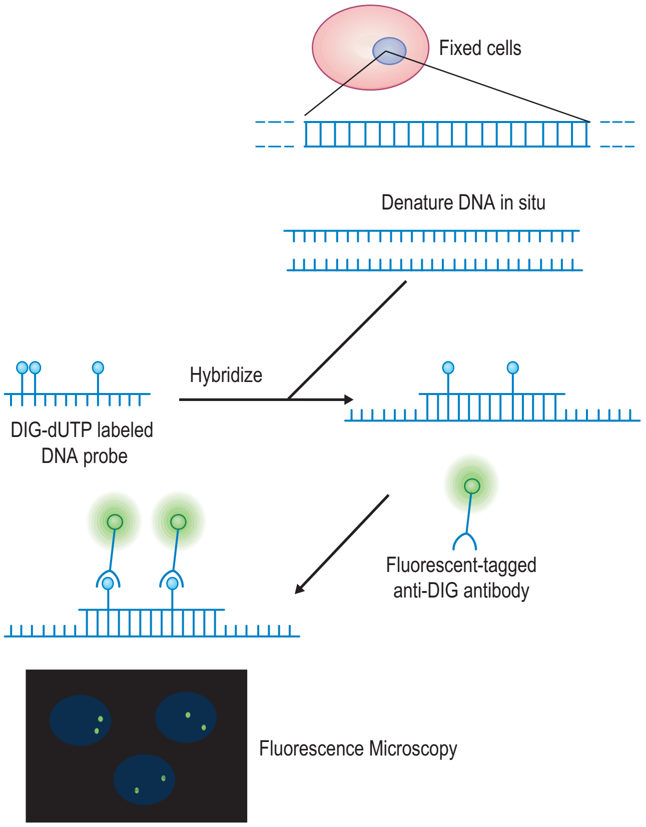

FIG 96.2 Fluorescence *in situ* Hybridization (FISH). Probes complementary to specific sites in the genome are labeled with a hapten (*e.g.,* digoxigenin) and then hybridized to denatured DNA within cells on microscope slides. The hybridized probes are then detected by immunofluorescence microscopy.

KEY CONCEPTS

Molecular Methods

- Most DNA diagnostics rely on DNA copy number analysis or DNA sequencing.
- Polymerase chain reaction (PCR) allows for exponential amplification of a DNA segment from the genome, allowing multiple analytical procedures on the single pure sequence.
- Array-based copy number analysis has become the first-line method for finding small abnormalities in the structure of chromosomes.
- New high-throughput sequencing methods have emerged as practical alternatives to older single analysis approaches.
- Bioinformatics is an emerging discipline relevant to molecular diagnosis. Integration of bioinformatics techniques plays a necessary role in data acquisition and interpretation.

Array-Based Copy Number Analysis

Oligonucleotide arrays have had a revolutionary impact on molecular diagnostics, by offering high-resolution, genome-wide detection of copy number changes. The basic principle involves synthetic oligonucleotides complementary to human nucleic acid sequences bound to a surface or bead, and hybridization of fragmented, labeled human nucleic acid samples (Fig. 96.3). Array printing of activated phosphoramidite nucleotide precursors allows for hundreds to thousands of oligonucleotides to be fabricated on activated glass surfaces (Agilent Technologies, Santa Clara, CA).[20] Light-activated oligonucleotide synthesis has also been used to efficiently customize oligonucleotide arrays (Affymetrix Inc., Santa Clara, CA; and Roche Nimblegen Inc., Madison, WI).[21] A third approach involves synthesis of oligonucleotides on microbeads that are randomly flowed over a patterned surface

FIG 96.3 Array-Based DNA Copy Number Analysis. (A) Array comparative genomic hybridization (aCGH) uses a reference DNA to compare with the test DNA. The labeled DNA is hybridized to an array of oligonucleotides that are designed to be uniquely complementary to hundreds of thousands of positions in the genome. The relative intensities of the fluorescence signal from each DNA probe allow assessment of copy number. Genotyping arrays are also widely used for copy number testing (B, C). (B) Whole genome sampling and amplification (WGSA). End-labeled polymerase chain reaction (PCR) products that constitute a sample from the genome are hybridized to oligo sets on standard chips. The oligos are organized into "probe quartets" consisting of perfect matches (PMs) and single-base mismatches (MMs) for each allele, A and B. Separate quartets for the sense and antisense strand of DNA help to ensure specificity, and in the actual assay these quartets are repeated three to five times on the chip. This type of assay has been developed to test a standard panel of >2 million DNA features per sample. (C) Single base extension (SBE; Illumina Infinium II). This assay uses whole genome amplification (WGA) to increase the molar concentration of target DNA. SBE on arrays of tagged microbeads allows allele discrimination, and the resulting products are detected by immunostaining (signal amplification). This assay has been used for assays of up to 5 million single nucleotide polymorphisms (SNPs) per sample.

(Illumina Inc., San Diego, CA).[22,23] These processes are very similar, in principle, to the fabrication of microelectronics devices, and so have given these arrays the nickname "gene chips."

Microarrays have been used in very-large-scale studies to genotype common polymorphisms. Robust chemistries that can analyze standard sets of up to 5 000 000 SNPs in a single assay are now routine (see Fig. 96.3). Nonamplified genomic DNA is too complex (*i.e.,* the concentration of any particular sequence is too low) to be analyzed directly. High-throughput genotyping assays require an array-based readout and scalable, multiplex assay chemistry. This is extremely challenging because of the complexity of the human genome (*i.e.,* any particular unique sequence in the mixture has a low molar concentration and because of the need for exquisite specificity at the single base level). An important general principle for achieving single-base specificity is the detection of physically coincident events.[24] This is exactly the route taken by the polymerase chain reaction (PCR), in which specific annealing of both primers is required for the reaction to take place (Fig. 96.4).

Whole genome sampling and amplification (WGSA) implemented in the Affymetrix SNP arrays uses parallel amplification of short DNA segments (200–1100 base pairs [bp]) that are then labeled and hybridized to oligonucleotide probe arrays.[25] The oligonucleotides are specific for each allele of SNPs, and the resulting hybridization intensities can be used to derive the genotypes. These assays are fixed in the sense that the investigator uses the information from a standardized array but cannot add SNPs for particular purposes. An alternative approach, incorporated in the Infinium assays (Illumina Inc., San Diego, CA), involves the detection of allele-specific primer extension or single base extension products on a self-assembling high-density microbead array.[26] In the Infinium assays, genomic DNA is first subjected to whole genome amplification (WGA), and those products are hybridized to an array of locus-specific 50-mer capture probes. Either primer extension or ligation reactions on the array surface are used to accomplish allele discrimination. Signal amplification with methods familiar to users of enzyme-linked immunosorbent assay (ELISA) is used to enhance the sensitivity. A distinct advantage of this class of assays is that the "assay conversion" (percent SNPs that actually allow inference of the genotype in the final assay mixture) is very high and thus allows for flexibility in designing tests customized to particular problems.

GENE EXPRESSION

Global gene expression analysis has been enabled by microarray technology giving rise to so called "transcriptomics." For RNA

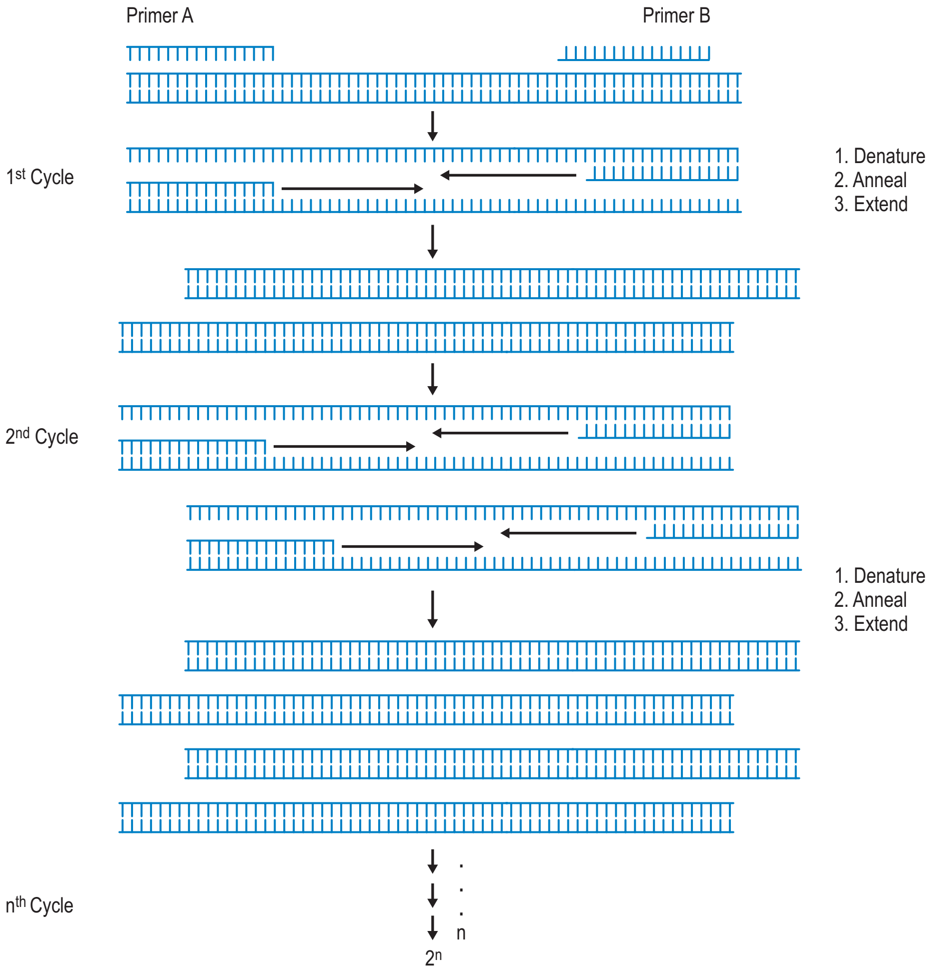

FIG 96.4 Polymerase Chain Reaction. Primers that hybridize to the target sequence are used to initiate multiple cycles of synthesis, melting, annealing, and synthesis. In practice, the potential geometrical increase in DNA tapers off as reaction components become limiting.

expression analysis, cDNA "target" derived from the tissue or cell source is labeled with fluorophores and used to determine complementary binding by massively parallel hybridization to the probes fixed on the array. The ability to massively sequence RNA (see below) from diverse biological samples has reduced use of arrays for research. RNA measurement, either by array or sequencing, has been slow to enter clinical practice. A major challenge lies in the variation between studies in sample selection, cell composition of samples, analysis platform, and statistical methods. Establishing criteria for analytical validity, clinical validity, and clinical utility are long-term challenges for use of gene expression biomarkers.

Detection of Disease Causing Mutations—Point Mutations, Insertions/Deletions, and Structural Variants

Methods for the detection of single-base substitutions in DNA are central to clinical genetic diagnostics.[27] Although complementary DNA (cDNA) synthesized from mRNA can be used, analysis of genomic DNA is far more common. Many different methods for mutation detection have been described, but virtually all clinical diagnostic laboratories now approach an unknown mutation with DNA sequencing. When Sanger sequencing is used, the first step is to design PCR primer sets that will allow amplification of each exon. The availability of the reference human genome sequence makes determination of gene structure and amplimer design for genomic DNA straightforward. Any mutation that directly affects amplification, such as deletion or mutation in the amplimer sequence, can produce misleading results. It is always desirable to have parental specimens available to serve as a reference for proving biallelic inheritance in the affected offspring. If there is a clear clinical diagnosis and only a single gene likely to be involved, then automated fluorescent sequencing is still the preferred method. For disorders with highly complex clinical and laboratory phenotypes, like primary immune deficiencies, the problem of locus heterogeneity is very severe. It is now routine practice to solve this problem by sequencing the complete exome or the complete genome in individual patients by using the next-generation technologies described below.

Sanger Sequencing

The direct determination of a DNA sequence is fundamental to mutation identification (Fig. 96.5). The oldest method still in common use (called *Sanger sequencing*) depends on termination of DNA synthesis by chemically modified nucleotides (dideoxyNTPs [ddNTPs]). A single-stranded DNA (ssDNA) template is hybridized to a primer that can recognize a short known segment of DNA. The ssDNA is usually produced by DNA amplification. The primer acts as a starting point for DNA synthesis by a DNA polymerase that is added to the reaction. Four separate reactions are set up, each "spiked" with one of the four possible ddNTPs (ddATP, ddTTP, ddCTP, or ddGTP). As synthesis proceeds, some of the strands incorporate a ddNTP, and no further extension can take place. In each reaction, a family of molecules is synthesized; their unit lengths are determined by whether the reaction had been terminated by incorporation of a specific ddNTP at a given position. Either the primer or the nucleotides may be labeled. Automated instrumentation for DNA sequencing using laser scanning of fluorophore-labeled reactions is standard. By using four different fluorescent labels the reaction products from one sample can be analyzed together, with many samples processed in parallel using renewable capillary electrophoresis arrays.

Next-Generation DNA Sequencing

New technologies that have dramatically increased the throughput and reduced the cost of DNA sequencing have been rapidly adopted in research and diagnostic laboratories. Unlike Sanger sequencing, which produces sequence data by controlled termination of the polymerase, the new techniques derive the sequence as nucleotides are sequentially added by the polymerase or interrogate the sequence by flow through nanopores. Although multiple chemistries and detection systems have been developed into sequencing instruments (Fig. 96.6), this discussion will review methods that have been adopted into clinically validated assays and also briefly describe two methods that, to date, have only been used in research but that illustrate the potential for very long reads. Such methods may have a role in better defining

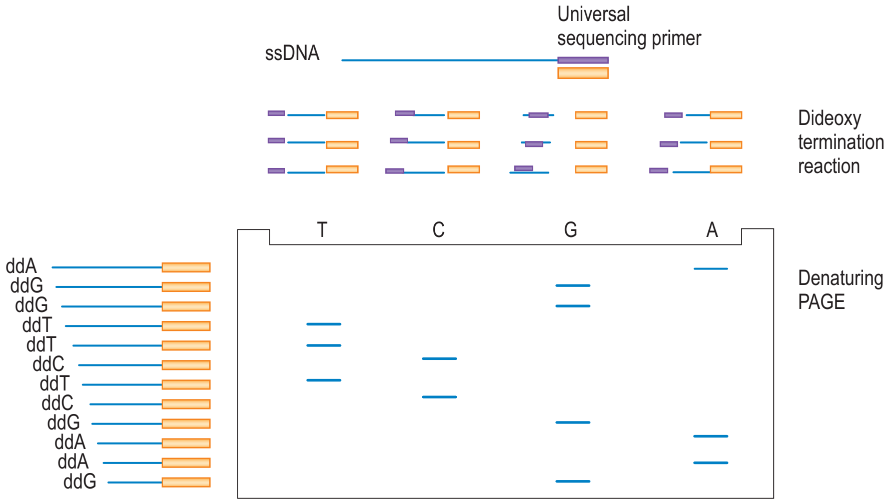

FIG 96.5 DNA Sequencing by Dideoxynucleotide (ddNTP) Chain Termination (Sanger). Copying of the DNA by the polymerase is terminated at specific positions when a ddNTP is incorporated. The ddNTP is mixed with deoxynucleotides (dNTPs) so that in each reaction, only some new strands terminate, whereas others continue through to the next complementary nucleotide. The sequencing products can be visualized by autoradiography or by laser scanning in an automated sequencer.

FIG 96.6 **Next-Generation DNA Sequencing.** (A) Sequencing by synthesis (Illumina Inc., San Diego, CA). This is a method in which fluorescent labeled terminator nucleotides are sequentially added and then imaged. After deprotection, another cycle of addition and imaging can take place. The currently available instrumentation allows simultaneous imaging of >1 billion "clusters" representing unique DNA elements. Approximately 100-150 cycles of base addition is commonly used. (B) Electrochemical sequencing (IonTorrent/Proton; ThermoFisher Scientific, Waltham, MA). This method is very different from all others currently available in that it does not use any fluorescence labels or imaging. Sequences are inferred by changes in electrical conductance caused by release of hydrogen ions when bases are added to a DNA chain. (C) Single-molecule sequencing (PacBio, Pacific Biosciences, Menlo Park, CA). In this method DNA polymerase is attached in a microscope imaging unit called a zero-mode waveguide (ZMW). A single DNA molecule is imaged as fluorescent nucleotides are added on the single-stranded template DNA. This method distinguishes itself by the very rapid rate of reaction and the very long read length achieved. (D) Nanopore sequencing uses protein nanopores arrayed in a membrane. DNA passing through the pore causes a slight disruption in the current making it possible to identify the base at each position in the sequence. Tether oligonucleotides and motor enzymes and tethers are used to attach the DNA to the pore and cause the DNA to move through the pore, respectively.

structural variants in DNA. In addition, an important recent application of next-generation sequencing (NGS) will be discussed, circulating cell-free DNA (cfDNA). This technology has already revolutionized pregnancy screening for common chromosomal disorders and may be adapted to screening for low levels of solid tumor DNA in blood.

Sequencing by synthesis (Illumina). The most widely used system for NGS involves highly parallel imaging of single base addition on "clusters" of identical DNA molecules (see Fig. 96.6A). This technology has been commercialized by Illumina Inc. (San Diego, CA). In their approach, DNA is ligated to primers that allow it to be amplified on a surface called a "flow cell."[28] The DNA templates attach to the flow cell surface by hybridization to specific primers complementary to that used to prepare the DNA library. Solid-phase bridge amplification creates many identical copies of each single template molecule in a localized cluster. The density of the clusters is extremely high, and the specialized imaging system allows resolution of more than 10^9 clusters per flow cell. DNA sequence is determined in the flow cell by sequential addition of fluorescent-tagged nucleotides. A single-labeled nucleotide is added to nascent DNA in each sequencing cycle. Each nucleotide has a different fluorophor so that all four are added to the mix in each cycle of base extension. The nucleotide label also terminates polymerization (*i.e.,* only a single base is added at each cycle), and the identity of the incorporated nucleotide is determined by the fluorescent emission spectrum and intensity. Because the bases act as terminators, homopolymeric segments can be resolved relatively accurately. After each deoxynucleotide (dNTP) incorporation, the fluorescent dye is enzymatically cleaved to allow incorporation of the next nucleotide. This class of instruments is capable of sequencing complete human genomes in a single run.

Electrochemical sequencing. Electrochemical sequencing (IonTorrent/Proton; ThermoFisher Scientific, Waltham, MA) is distinctly different from systems that image fluorescent-tagged nucleotides because the sensor is a microelectronic device (see Fig. 96.6A).[29] DNA is first fragmented and then ligated to adapters, and the adaptor-ligated libraries are clonally amplified by emulsion PCR onto beads. Individual beads are then loaded into single-sensor wells. Nucleotides are provided in a stepwise fashion with incorporation increasing the length of the sequencing primer by one base when there is a complementary base on the template strand. Sequence determination relies on primer extension. Nucleotide incorporation into a nascent DNA strand by DNA polymerase results in hydrolysis of the nucleotide triphosphate. Hydrolysis causes production of a hydrogen ion for each nucleotide incorporated. The small shift in the pH of the surrounding solution is proportional to the number of nucleotides incorporated, which is then detected by the sensor on the bottom of each well, converted to a voltage, and digitized by off-chip electronics. The chip is automatically washed, and the cycle is repeated with the next nucleotide. Because of the small size of the wells, diffusion into and out of the well is very fast. The sensor layer is composed of tantalum oxide, which is sensitive to proton concentration (essentially pH) allowing rapid detection of the voltage transients that follow base incorporation in each well individually. The voltage change is roughly proportion to the length of a run of the same nucleotide in the DNA so that short homopolymers can be accurately called. Chip fabrication and design are very similar to methods used for microelectronic devices. This suggests that the method will have good potential to scale up to increase the number of molecules processed in parallel. Lacking optical components, the cost of the all-electronic detection system is far less than other sequencing instruments.

Long read sequencing—single-molecule sequencing and nanopores. A true single-molecule sequencing method has been developed by Pacific Biosciences (Menlo Park, CA).[30] In their method DNA polymerase is immobilized in a femtoliter-sized well with special optical properties called the zero-mode waveguide (ZMW) (see Fig. 96.6C). The small size of the ZMW "hole" prevents 600-nm wavelength laser light from passing entirely through, and only the bottom 30 nm where the polymerase is bound is subject to the fluorescence excitation. Labeled nucleotides are flowed into the chamber and complementary bases encountering the DNA polymerase are incorporated into the growing DNA chain. During incorporation, the DNA polymerase holds the nucleotide for tens of milliseconds, orders of magnitude longer than the average diffusing nucleotide. The transient light emission is then detected and the identity of the incorporated base recorded. Nucleotides with a fluorescent dye attached to the phosphate group of the nucleotide are cleaved when the nucleotide is incorporated into the DNA strand. The label diffuses away, leaving the DNA ready for the addition of the next base. The polymerase incorporates multiple bases per second, so the sequencing process is very fast with real-time observation of DNA synthesis.

Engineered nanopores are being evaluated for the detection of a broad array of biomolecules, including proteins and nucleic acids.[31] There are many potential variations in pore, sample preparation, and detection, which have given rise to active academic and commercial research programs. In one effective version, a protein channel (*e.g., Mycobacterium smegmatis* porin A, MspA) through which DNA may pass is held in a partition (membrane or other solid) that separates solutions containing charged ions. An applied voltage leading to movement of ions through the protein pore produces a measurable electrical current. DNA passing through the channel causes partial reduction of the current with the four DNA bases affecting the current by differing and characteristic amounts (see Fig. 96.6D). The changing electrical current is then used to infer the order of bases in the DNA molecule. Oxford Nanopore Technologies (Oxford, UK) released the first commercial devices based on this technology, and the uses are under active investigation. One of the most important strengths of this method is the very long single-molecule reads that can be obtained. High read depth can partially overcome problems with sequence accuracy (per base error rates of 10–30%). The fast run times and simple protocols for sample preparation have allowed an early stage instrument to be used to sequence Ebola virus on site in Africa. Because of the speed of analysis, "bedside" medical applications could be feasible (especially when base error rate is of less importance for the intended use) and appears especially promising in the arena of precision diagnosis of infectious diseases.

BIOINFORMATICS

Clinical Bioinformatics has emerged as a fundamental discipline in laboratory medicine as enormous DNA sequence, transcriptomics, and variant databases have been aggregated from individual laboratories and international genomics projects. The growing number of genetic loci that are already known to be important in immunological disease renders it critical that diagnostic laboratories make maximal use of automated processes in sample management, data acquisition, data analysis, and reporting. Laboratories using NGS instruments must establish an informatics pipeline for each clinical application. New assay development requires validation conforming to Clinical Laboratory Improvement Amendments of 1988 (CLIA 1988) regulations and laboratories must have an ongoing process to monitor data quality and ensure result accuracy. The US Food and Drug Administration (FDA) has released a draft guidance on standards for clinical NGS-based diagnostic tests (http://www.fda.gov/ucm/groups/fdagov-public/@fdagov-meddev-gen/documents/document/ucm509838.pdf).

Sample and Laboratory Process Management

Each diagnostic laboratory must deal with the generic operational problems of sample accession, tracking, and reporting. Clinical-grade laboratory information management systems (LIMS) are required to handle all these processes with associated regulatory compliance. DNA diagnostic laboratories have several unique problems and requirements that deserve comment. Automated data acquisition is an important component of DNA sequencing and genotyping requiring personnel specialized in information science and systems administration. Advanced statistical models are employed at many steps in the processes of base calling (*primary analysis*), alignment to the reference genome, and identification of positions that are different from the reference (together called *secondary analysis*). Once the raw data from arrays and NGS are produced, bioinformaticians develop, manage, and operate analysis pipelines that synthesize the results into forms comprehensible to the laboratory staff tasked with reporting the results. Bioinformaticians maintain or develop analysis information management systems (AIMS), which are also used to collect and monitor performance metrics and quality control. Specialized software is used to perform these functions and to report the metrics needed for quality control. The number of patient-specific data records and the complexity of relationships in family-based testing make it essentially impossible for manual processes to achieve the required reliability. Because of the broad intended use of genomic testing, there is an increasing importance to collection of patient phenotype data, which is needed for variant filtering and prioritization (see *Tertiary analysis* below).

Primary Data Analysis—Genotyping and Base Calling

Genotyping in the case of microarray and base calling in the case of sequencers are platform specific, and the required software is supplied by instrument vendors. Microarray data, whether array comparative genomic hybridization or SNP chip platforms, use signal hybridization intensity to estimate DNA copy number. Copy number calls are based on multiple adjacent assay positions with respect to the genome map (*i.e.,* the identification of clinically important CNVs is always supported by many independent data points and on-chip assay replicates). The resolution and reliability of the CNV calls depends on total number of positions on the array and their "responsiveness" to differences in DNA copy number. Laboratories using these methods must assess data quality with robust statistical procedures specifying in advance the minimum size and composition of called CNVs.

Sequencing data, especially when considering exome and whole genomes, presents much more challenging problems in bioinformatics. Base calling from the instrument raw data (primary analysis) typically takes place in local computers dedicated to the sequencer, but cloud-based methods can be used. Base calling generates sequence "reads" with their base quality scores. Some of the important measures of data quality at the primary analysis step are base quality score, number of reads per sample, length of reads, and fall-off of base quality with read position.

Secondary Data Analysis—Demultiplexing, Alignment, and Variant Calling

The next steps in next-generation sequence data analysis involve aligning reads to a reference sequence and generating variant calls. In many high-throughput applications, patient DNA samples are tagged with index sequences during preparation for sequencing (*library construction*). Molecular indexing or multiplexing allows pooling of the samples on the instrument and then sorting them out after sequencing. Demultiplexing of sequence reads is another step that is subject to quality monitoring.

After demultiplexing, the reads are mapped and aligned to the reference genome. Alignment of short-read sequences to the reference genome involves systematically matching read fragments to their correct location in the genome. The most widely used tools exploit the Burrow-Wheeler algorithm to carry out this process efficiently and precisely (bio-bwa.sourceforge.net/). Typically, only uniquely mapping reads are passed to the later steps of sequence analysis. This makes it difficult to analyze some segments of the genome that are important in health and disease. Some elements in the genome are composed of nearly identical sequences most often arranged in tandem on adjacent segments of chromosomes. Human leukocyte antigen (HLA) presents particular challenges: *(i)* certain HLA alleles may not be represented in the reference genomes; *(ii)* reads may align to more than one location in HLA leading to discard of the read or misalignment and false-positive variation; and *(iii)* identical reads may have origins in distinct haplotypes that cannot be easily recognized with short-read sequences.

Another important issue is that the reliability of variant calling is different with different classes of variation. Small insertion and deletion variants (indels) are clinically important because they often lead to frameshift and premature termination of proteins; but calling indels and automated application of consistent indel nomenclature are more difficult than single nucleotide variants (SNVs). The Genome Analysis Toolkit (http://www.broadinstitute.org/gatk/) is the most widely used software for variant calling.

Targeted resequencing and whole exome sequencing (WES) focus on protein-coding elements in the genome. Because of the complex and highly variable exon–intron structure of genes, there is considerable technical difficulty in using exon sequence data to call structural variants and CNVs. WGS, in contrast, surveys all the intron and intergenic sequence. New methods of PCR-free library construction enable the read count depth to be used as an accurate surrogate for copy number.[32] In addition, gaps in aligned reads (called "split reads") can be used to recognize deletions and other structural variants, including duplications and inversions. Although challenges still remain, it is possible that WGS data combined with standardized algorithms could allow a single test to be used for almost all classes of pathogenic alleles.

Variants are saved in a specified format called a *genomic variant call format (gVCF) file.* This format contains information not only about the positions that contain a nonreference genotype call but also about the quality of each site that is called with the reference homozygous base. This is important because it allows multiple samples to be aggregated (*e.g.,* to analyze mother, father, and their offspring jointly). Format standardization allows exchange and aggregation of data among laboratories around the world. Data aggregation is now widely recognized as a key step in the development of molecular diagnostics, not only to reduce errors in variant calling but also to enable sophisticated approaches to the problem of genotype-phenotype relationships in rare genetic diseases.

Tertiary Data Analysis—Variant Annotation, Interpretation, and Reporting

The next steps in the analysis involve annotation, filtering, and classification of variants as to their likely role in the disease or phenotype for which the test was submitted. The laboratory must ensure that the final report is accurate and complete without overinterpretation. Annotation of each variant detected in the sequencing means attaching information about population frequency (or lack of previous observation), differences in frequency between various ethnic groups, effect of the variant on protein coding sequence, effect on splicing, and so on. Diagnostic laboratories must actively use information contained in the public sequence databases to interpret the biological consequences of mutations and polymorphisms. There are databases that have an important role: *(i)* GenBank, which contains the reference human genome sequences (http://www.ncbi.nlm.nih.gov/entrez); *(ii)* dbSNP, which contains more than 150 000 000 common single-nucleotide polymorphisms; *(iii)* Exome Sequencing Project (https://esp.gs.washington.edu/drupal/), which has exome data on about 6500 individuals from several research projects; *(iv)* the 1000 Genomes Project (http://www.1000genomes.org/), which has exome and genome data from about 2500 multiethnic controls; and the *(v)* Exome Aggregation Consortium (http://exac.broadinstitute.org/), which has assembled variant data on more than 60 000 subjects from various disease and populations studies.

Interpretation of sequence and genotype information is the next step in carrying out a molecular diagnostic test. The laboratory must do the following: take into consideration the patient's presenting symptoms and other clinical data; examine the strength of the evidence that specific gene mutations can cause the suspected disease; look for variants in genes that might provide a causal explanation; determine whether a candidate variant has previously been reported to cause a disease; determine whether variants that appear in previous databases have a low frequency (*i.e.*, compatible with the observed frequency of the rare disease); determine whether loss-of-function, gain-of-function, dominant negative, haploinsufficiency, and so on are known underlying mechanisms of disease; determine whether variant occurs in an exon and/or protein domain compatible with alteration of function; and summarize whether the candidate variants occur in similarly affected family members (pattern of inheritance and cosegregation). If a variant has been observed in the proband and other family members are tested, then the expectation is that it will exactly segregate with the disease. An example would be testing for a mutation in X-linked SCID in two brothers. The causal variant will be present in both. When the proband is the only affected individual, then one may look to the literature; ClinVar (www.clinicalgenome.org/data-sharing/clinvar/), a database of variants with curated interpretations; and locus-specific public databases (bioinf.uta.fi/base_root/mutationdatabases.php) to determine whether the specific variant has previously been observed in another affected person. However, it is routine to find variants that have not previously been observed. Assessment of the functional consequence of a newly observed sequence variant is problematic, as there is no guarantee that it is anything more than a rare, but neutral, polymorphism. Loss-of-function mutations (*e.g.*, nonsense, frameshift, and conserved splice site mutations) have clear functional consequences. Missense substitutions are more difficult. Several methods based on sequence conservation and the chemical properties of amino acids have been developed. These are available in software, such as Sorting Intolerant From Tolerant (SIFT) (http://blocks.fhcrc.org/sift/SIFT.html), PolyPhen (http://coot.embl.de/PolyPhen/), and several others. CADD represents a class of software that creates a joint model based on integration of many of these methods.[33] All these criteria are put together in a process called *gene and variant curation.* Recommendations for scoring variants into five categories—pathogenic, likely pathogenic, variant of unknown significance, likely benign, and benign—have been given by the American College of Medical Genetics and Association for Molecular Pathology.[34]

The next step in the process is assembly of filtered and classified variants into the laboratory report. The report must be simple enough for physicians who are not experts in genomics to understand but, at the same time, must document the intermediate results required to demonstrate analytical accuracy and clinical validity. Clinical reports must contain clear nomenclature for the position and consequence of relevant variants along with appropriate indication of test and interpretive limitations. The final steps of interpretation and reporting may be facilitated by communication with the referring clinician so that there is active collaboration in arriving at a clinical diagnosis.

The final steps in bioinformatics management of NGS tests are aggregation and data sharing. Submission of deidentified cases to public-knowledge databases, such as ClinVar, will allow aggregation of variant data accompanied by sufficient clinical information to support variant classification. Once this information is accumulated in many clinical contexts, the value for patient care will be magnified beyond what could be inferred from the case data alone. Data sharing that is consistent, standardized, and collected with appropriate protections for confidentiality will be an invaluable resource for the future.

Clinical Performance of Genomics Assays

The development of specialized training programs in molecular genetics and molecular genetic pathology by the American Boards of Medical Genetics and Pathology[35] highlights the recognition by professional groups that this area of clinical testing is exceptionally complex. Although inferences made about disease diagnosis and carrier status based on direct detection of mutations are inherently categorical, data interpretation should incorporate known genotype–phenotype correlations, variable disease expression/severity, incomplete penetrance, gender-specific risk, and other available data. In the future, as DNA testing is employed in the assessment of more complex traits such as autoimmune and neoplastic diseases, genotype data will perhaps be expressed as "relative risk" and incorporate gene–gene and gene–environment interactions. The reliability of these estimates will require standard data acquisition algorithms and constant updating of population-based data.

RECOMMENDATIONS FOR USE

KEY CONCEPTS

Principles of Molecular Diagnostics

- DNA diagnostics can play an important role in the diagnosis of specific diseases in affected individuals and in genetic risk assessment for their family members.
- Genotyping can be used to conduct prenatal diagnoses.
- Prenatal diagnosis may be used not only for elective termination of pregnancy but also for treatment planning.
- Provision of genetic testing results to patients and their families carries responsibilities for sensitivity and confidentiality.

Clinically Important Applications of Next-Generation Sequencing

Molecular diagnostic techniques have a wide range of potential applications in clinical immunology. DNA diagnostic procedures are used to *(i)* perform HLA genotyping; *(ii)* analyze and monitor neoplastic disease; *(iii)* provide identification or DNA "fingerprinting"; *(iv)* monitor bone marrow engraftment; *(v)* establish a genetic diagnosis in a symptomatic individual; *(vi)* determine the risk of occurrence of a disease in offspring; and *(vii)* to establish a prenatal diagnosis. The use of DNA analysis for HLA typing is described in Chapter 5. DNA techniques are used in leukemias and lymphomas, primarily for investigation of cell lineage, proliferative clonality, and measurement of residual abnormal cells after therapy. Molecular analysis, and especially molecular cytogenetic analysis, is important in guiding initial and follow-up therapies (Chapters 78 and 79).

Targeted Panels

When the phenotype is sufficiently circumscribed that a limited list of genes is known to account for a high percentage of cases, it may be appropriate to use a targeted gene panel as the first-round genetic diagnostic test. The reasons include assay design strategy that puts maximum emphasis on complete gene coverage; lower unit cost of testing; and reduced occurrence of secondary findings (*i.e.,* apparently pathogenic variants in genes not suspected from the primary indication for testing). But efficient use of targeted panels requires high sensitivity in the sense that most of the important disease-causing genes must have been accounted for and give a conclusive diagnosis in a large fraction of clinical cases. This situation is often not met because of the lack of specificity in clinical presentation or the very large degree of locus heterogeneity. The latter is particularly important in PIDs.

Whole Exome/Whole-Genome Sequencing

In the past, clinical genetic testing would necessarily stop after the most likely genes had been investigated in a few targeted laboratory tests. That strategy changed in the last few years after it became possible to efficiently assess most known disease genes in a single test. Two approaches are in use today: WES and WGS. WES depends on "capture" of the 1–1.5% of the genome that contains the protein-coding segments of genes. Capture is typically achieved by liquid phase hybridization followed by PCR and sequencing library construction. The rationale for WES is that most interpretable disease causing variants occur in coding sequence, and thus the sequencing is focused on the interpretable fraction of the genome. The lower unit cost of WES also allows for greater read depth with concomitantly lower error rates. Some significant limitations of WES include incomplete coverage of disease-causing genes because of inefficient capture; uneven coverage across all targeted regions such that adding more read depth inefficiently adds to poorly covered regions; poor ability to resolve structural variants; limited ability to call copy number variants; and inability to call triplet repeat mutations. WGS, especially when implemented with PCR-free library construction techniques, overcomes most of these limitations. The falling cost of WGS, especially when coupled to automated library preparation systems, holds the promise of nearly complete analysis of the genome of individuals.

Cell-Free DNA and Liquid Biopsy

It has been known for many years that there is normally a small amount of genomic DNA in the cell-free plasma fraction of blood (called *cfDNA*). It is thought that this material comes from the normal processes of cell apoptosis, particularly from leukocytes. During pregnancy, there is a significant contribution of DNA from the placenta, and thus cfDNA can be used as a biological surrogate for the fetal genome. NGS enables sampling of this DNA at very high read depth, and common chromosomal imbalances in the fetus can be detected by analysis of DNA extracted from maternal plasma. The observation of a patient who had cancer during pregnancy led to the discovery that cancer cells may also contribute to cfDNA. New genomic assays for detection of cancer recurrence, changes in mutation spectrum, and clonal expansion are rapidly arriving in clinical practice. These assays are likely to be especially useful in lymphomas and other solid tumors that have required invasive biopsies. Serial testing by these so called liquid biopsy methods is very likely to have a large impact in immune-oncology practice.

LABORATORY STANDARDS AND REPORTING

All US laboratories providing any clinical data are subject to the regulatory requirements embodied in CLIA88.[36] CLIA88 mandates biannual laboratory inspections, quality control, quality assurance, proficiency testing, and personnel training standards. The American College of Medical Genetics has also produced guidelines for diagnostic laboratories conducting molecular genetics testing. A clear argument can be made for the clinical utility of early diagnosis for rare diseases, but demonstrating reduced cost of care or improved clinical outcome is difficult. Genomics tests, like all diagnostic testing, should be designed and developed such that the practiced test can meet the requirements of its intended use. The performance of genomic tests must be validated before they are offered for clinical diagnostic use. Critical measures of performance include sensitivity—how often the test is positive when a disease causing variant is present; specificity—how often the test is negative when a mutation is not present; "technical" positive predictive value (TPPV)—the fraction of true positives divided by the sum of the true positive and false-positive tests; and positive and negative percent agreement (PPA) with previous reference standards. These are all measures recommended by the FDA in its draft guidance for validating clinical NGS tests. New methods to test and validate bioinformatics software are also needed as the field moves forward (Fig. 96.7).

FUTURE DIRECTIONS

The next decade will bring further improvements in our ability to identify family-specific pathogenic variants for all genes that cause rare mendelian disorders, such as PIDs. Sequencing technology will continue to develop, further reducing the cost of genome analysis for individuals and families. As our understanding of the role of polymorphisms in disease risk increases, the importance of low-cost, high-throughput genotyping of standard variant panels will also increase.[37] The importance of bioinformatics in data analysis will become increasingly apparent as large amounts of individual sequence data are produced. International clinical variant databases will play an important role in both diagnosis and prognosis. New statistical approaches will be needed to exploit fully the potential of complete genome sequence for estimation

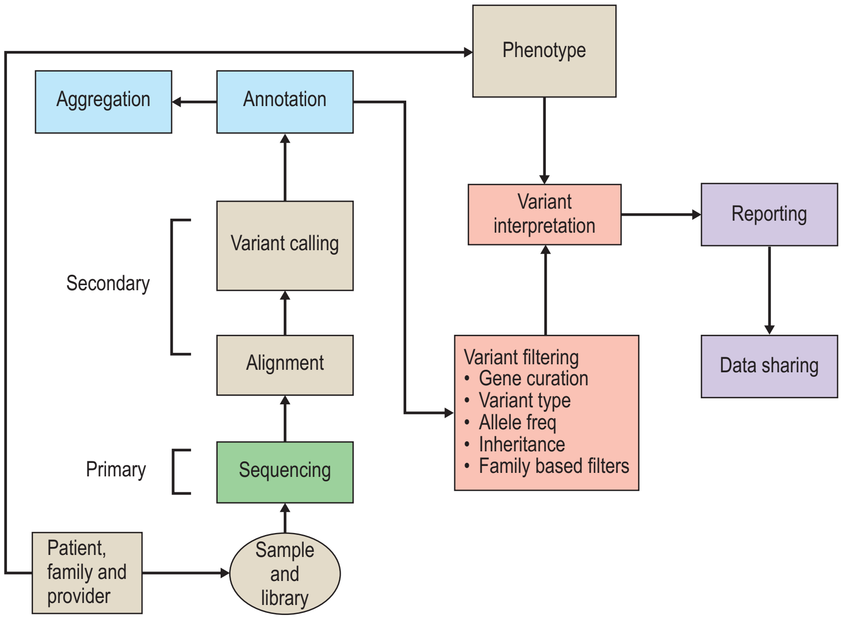

FIG 96.7 **Clinical Bioinformatics.** Primary, secondary, and tertiary phases of data analysis and reporting.

of disease risk. Prospective screening of newborns for the T-cell immune deficiencies is feasible.[38,39] Although rare, these are treatable disorders whose prognosis would be altered by early diagnosis before the onset of serious infection. In aggregate, the birth incidence is sufficient to merit screening if the techniques could be interfaced with current state screening programs. Screening for premalignant genotypic changes in peripheral blood might also be a reality one day. Careful clinical studies, including examination of the costs and benefits of mass screening programs, will be essential.

ON THE HORIZON

- Routine diagnosis of >300 primary immunodeficiencies by whole-genome sequencing
- Rapid discovery of new primary immune deficiency genes by whole genome sequencing in individual families
- Preconceptional screening to identify carrier status for thousands of genetic disorders
- Noninvasive prenatal screening of fetal DNA in maternal blood for copy number abnormalities and mutations

TRANSLATIONAL RESEARCH AND CLINICAL APPLICATION

DNA sequencing technology is evolving very rapidly, and we can anticipate additional technical platforms to become available over the next decade. Massive increases in sequence output, speed of sequencing, increases in read length, and more efficient bioinformatics methods will fuel further reductions in cost. Complete genome sequencing will likely become a first-line medical test for the diagnosis of most suspected genetic disorders, including the PIDs. Gene identification in single families with previously undescribed immune deficiencies will become routine. Personal complete genome sequencing for preconceptual genetic screening in the general population will become available and will impact risk counseling for thousands of patients with autosomal recessive and X-linked disorders. By analysis of either free DNA in maternal serum or circulating fetal cells, complete genome sequencing will provide a comprehensive testing platform for noninvasive prenatal diagnosis. Incorporation of other methods, such as RNA sequencing, will undoubtedly become part of routine functional assessment of suspected pathogenic variants. Single-cell sequencing technology promises to give much greater detail on the beautifully complicated problem of immune cell heterogeneity. Although single-cell sequencing has not yet been shown to have role in clinical diagnostics, it may present the next step in the long-term goal of understanding immunological diseases at the cellular level.

MULTIPLE-CHOICE QUESTIONS

1. Population screening for carrier status in genes that cause primary immunodeficiencies (PIDs) is made more difficult by:
   A. The prominent role of triplet repeat expansions among causative mutations
   B. Most primary immune deficiencies being inherited as autosomal dominant traits
   C. A large number of different genes (locus heterogeneity) and many very rare pathogenic variants (allelic heterogeneity)
   D. Most carriers coming from populations with a history of consanguinity

2. In the workup of a newborn with congenital heart disease, hypocalcemia, and absent thymus, the optimal testing approach is:
   A. Fluorescent *in situ* hybridization (FISH) for 22q11 microdeletions
   B. Array comparative genomic hybridization (aCGH)
   C. Sanger sequencing of the *TBX1* gene
   D. Next-generation sequencing whole exome sequencing

3. Next-generation sequencing (NGS) diagnostics used many bioinformatics methods, including:
   A. Base calling from raw instrument data (primary analysis)
   B. Demultiplexing, alignment to the reference genome, and variant calling (secondary analysis)
   C. Annotation of variants for their predicted effect on proteins and splicing
   D. Classification of variants for their likely role in causing disease
   E. All of the above

APPENDIX 1

Selected CD Molecules and Their Characteristics

Thomas A. Fleisher

CD Molecule	Predominant Distribution	Identity/Function
CD1a–e	Thymocytes, subset of lymphocytes, antigen-presenting cells	MHC class I–like molecules; presentation of nonpeptide antigens to T cells; thymic T-cell development
CD2	T cells	Binds to LFA-3; receptor for CD48; T-cell activation; adhesion
CD3	T cells	T-cell signaling complex; associated with TCR
CD4	T-cell subset	TCR coreceptor; interacts with MHC class II molecules on antigen-presenting cells; identifies T cells with helper function; signal transduction
CD5	Most T cells, thymocytes, B-cell subset	Binds to CD72; regulation of cell proliferation/activation; identifies B-1 B-cell subset
CD6	Thymocytes, T cells, B-cell subset	Binds CD166 (ALCAM); adhesion; mediates binding of developing thymocytes with thymic epithelial cells; thymic development; T-cell activation
CD7	Pluripotent hematopoietic cells, thymocytes, T cells	T-cell and NK-cell development
CD8	T-cell subset	TCR coreceptor; interacts with MHC class I molecules on antigen-presenting cells; identifies T cells with cytotoxic function
CD10	B cells	Neutral endopeptidase; enkephalinase; B-cell development; common acute lymphoblastic leukemia antigen (CALLA), neutrophils
CD11a	Leukocytes	α-chain of LFA-1; pairs with CD18; interacts with ICAM; adhesion and cellular migration
CD11b	Monocytes, granulocytes, NK cells	α-chain of complement receptor type 3 (CR3); pairs with CD18; adhesion molecule
CD11c	Monocytes, granulocytes, NK cells	α-chain of complement receptor type 4 (CR4); pairs with CD18; adhesion molecule
CD13	Hematopoietic stem cells, immature and mature myeloid and monocyte elements	Appears before CD33 during myeloid differentiation
CD14	Granulocytes, monocytes/macrophages	Receptor for LPS/LPB complex; myeloid differentiation antigen; cell activation
CD15	Neutrophils, eosinophils, monocytes, basophil subset	Sialyl Lewis X antigen, plays a role in cell adhesion, defective in leukocyte adhesion deficiency type 2
CD16a,b	NK cells, monocytes/macrophages, neutrophils	FcγRIIIA and FcγRIIIB (low-affinity IgG receptors-type III); phagocytosis; ADCC
CD18	Leukocytes	β-chain of β_2-integrin molecules, including LFA-1, CR3, and CR4; pairs with CD11a, b, and c
CD19	B cells	BCR coreceptor; signal transduction; complexes with CD21, expressed pre-B cells
CD20	B cells	Role in B-cell activation/differentiation
CD21	B cells; follicular dendritic cells	Complement receptor type 2 (CR2): C3d receptor; B-cell coreceptor subunit; EBV receptor
CD22	B cells	Associates with BCR; signaling; regulation of B-cell activation; adhesion
CD23	B cells, macrophages, eosinophils, platelets, follicular dendritic cells	FcεRII; (low-affinity IgE receptor), activated B cells
CD24	Leukocytes	Heat-stable antigen; costimulation; adhesion
CD25	Activated T cells and B cells	α-chain of IL-2 receptor, low-affinity IL-2 binding; signaling for cell proliferation/differentiation
CD26	Activated T cells and B cells; macrophages	Dipeptidyl peptidase; role in extracellular adhesion; cell activation
CD27	T cells; B-cell subset	Costimulation; T-cell proliferation, memory B cells
CD28	T cells	Binds B7-1 (CD80) and B7-2 (CD86); T-cell costimulation; signal transduction
CD29	Leukocytes	Integrin β_1-chain; pairs with CD49a-CD49f to form VLA-1-VLA-6 integrins, respectively; adhesion; signal transduction; development
CD30	Activated B cells and T cells	Binds to CD153; T-cell activation/regulation/differentiation, Reed–Sternberg cells
CD31	Monocytes, granulocytes, platelets, endothelial cells, B cells Recent thymic emigrants	PECAM-1; binds to CD38; adhesion; signal transduction
CD32	B cells, monocytes/macrophages, granulocytes, eosinophils	FcgRII (low-affinity IgG receptor-type II) phagocytosis; ADCC; B-cell regulation
CD33	Myeloid progenitors, granulocytes	Binds sialic acid
CD34	Hematopoietic progenitor cells; capillary endothelium	Mucosialin; binds to CD62L; adhesion

Continued

CD Molecule	Predominant Distribution	Identity/Function
CD35	Leukocytes; erythrocytes	Complement receptor 1 (CR1); C3b and C4b receptor; phagocytosis
CD36	Monocytes/macrophages; endothelium; platelets	Binds oxidized LDL; scavenger receptor; binds apoptotic cells; adhesion and endocytic receptor; GPIIIb; platelet adhesion and aggregation
CD38	NK cells; T-cell and B-cell subsets; monocytes	Binds CD31; cyclase; hydrolase; cell activation
CD40	B cells; antigen-presenting cells	Binds CD154 (CD40 ligand); B-cell proliferation, differentiation, and survival; T-cell costimulation
CD41	Megakaryocytes/platelets	Glycoprotein IIb; a IIb integrin chain; binds fibronectin, fibrinogen, von Willebrand factor, thrombospondin; extracellular adhesion; platelet aggregation
CD43	Leukocytes (except resting B cells)	Leukocyte sialoglycoprotein; may bind CD54; signal transduction; adhesion; antiadhesion
CD44	Leukocytes; memory T cells; erythrocytes	Binds hyaluronan (H-CAM), collagen, fibronectin, laminin, osteopontin; extra- and intercellular adhesion; T-cell costimulation; leukocyte homing
CD45	Leukocytes (pan-leukocyte marker)	Protein tyrosine phosphatase; cell differentiation; lymphocyte signal transduction and activation
CD45RA	Naive T-cell marker (in conjunction with CD62L); B cells, monocytes	CD45 isoform
CD45RB	B-cell and T-cell subsets, monocytes/macrophages, granulocytes	CD45 isoform
CD45RO	Memory and activated T cells; B cells, monocytes/macrophages	CD45 isoform
CD46	Hematopoietic cells	Membrane cofactor protein (MCP); binds to C3b and C4b and regulates complement pathway
CD47R	Leukocytes; endothelium	Integrin-associated protein (IAP); leukocyte migration, extravasation, and activation
CD48	Leukocytes (not neutrophils)	Binds CD2; adhesion; costimulation
CD49a–f	Various distributions	Integrin a1-6 chain; binds to CD29 to form VLA-1 to VLA-6; binds extracellular matrix components such as fibronectin, laminin, collagen (CD49D binds VCAM-1, fibronectin, MAdCAM-1, invasin); lymphocyte homing; extracellular adhesion; embryonic development
CD50	Thymocytes, B cells, T cells, monocytes, granulocytes	ICAM-3; adhesion
CD51	Platelets/megakaryocytes, granulocytes, monocytes, T cells	Integrin α-chain; associates with CD61; binds vitronectin, fibronectin, fibrinogen; extracellular adhesion; T-cell costimulation; epithelial inflammatory response
CD52	Leukocytes	GPI linked, signaling, defined by CAMPATH-1
CD54	Broad distribution; increased on activated leukocytes	ICAM-1; binds LFA-1; adhesion; leukocyte transendothelial migration, rhinovirus receptor
CD55	Hematopoietic cells and some nonhematopoietic cells	Decay accelerating factor (DAF); binds complement fragment C3b; regulation of complement activation
CD56	NK cells, NK-T cells	NKH-1; adhesion
CD57	NK cells, T-cell subset, B cells, monocytes	Oligosaccharide expressed on cell surface glycoproteins
CD58	Hematopoietic cells and non-hematopoietic cells	LFA-3; binds CD2; adhesion; lymphocyte coactivation
CD59	Hematopoietic cells and non-hematopoietic cells	Binds complement components C8 and C9 and regulates assembly of complement membrane attack complex
CD61	Platelets/megakaryocytes, macrophages	Integrin β_3 subunit; associates with CD41 or CD51
CD62E	Endothelium	ELAM-1 or E-selection; binds sialyl-Lewis X; adhesion; mediates rolling interaction of neutrophils on endothelium and neutrophil extravasation
CD62L	B cells, T cells, monocytes, NK cells	LECAM-1, LAM-1 (or L-selectin); binds CD34 and GlyCAM; adhesion; mediates rolling interactions with endothelium and call extravasation
CD62P	Platelets/megakaryocytes, endothelium	P-selectin; binds sialyl-Lewis X; mediates interaction of platelets with neutrophils and monocytes; mediates rolling interaction of neutrophils with endothelium
CD64	Monocytes/macrophages, mature neutrophils	FcγR1 (high-affinity IgG receptor)
CD65	Neutrophils, eosinophils, basophils monocyte subset, CD56 bright NK cells	During myeloid differentiation it appears after myeloperoxidase, appears to be the ligand for CD62L
CD66c	Differentiating myeloid cells peaks at promyelocyte stage, subpopulation of monocytes	Member of the carcinoeEDryonic antigen (CEA) family
CD68	Monocytes/macrophages	Macrosialin; early activation antigen; role in phagocytic activity
CD69	Activated T cells, B cells, macrophages, NK cells	Early activation antigen; costimulation
CD70	Activated B cells and T cells; macrophages	Binds to CD27; costimulation
CD71	Activated leukocytes, erythroid precursors	Transferrin receptor; cell activation
CD72	B cells	Ligand for CD5; B-cell activation and differentiation; costimulation

CD Molecule	Predominant Distribution	Identity/Function
CD73	B-cell and T-cell subsets	Ecto-5′ nucleotidase; allows nucleoside uptake
CD74	MHC class II expressing cells	MHC class II–associated invariant chain; involved in antigen processing and peptide presentation in antigen-presenting cells
CD77	Germinal center B cells	Entering apoptosis
CD79a,b	B cells	Iga, Igb; components of BCR complex that mediate signal transduction
CD80	Monocytes/macrophages, dendritic cells, activated B cells	B7-1; ligand for CD28 and CTLA-4; T-cell interaction with antigen-presenting cells; costimulation
CD81	Lymphocytes	Associates with CD19 and CD21 to form B-cell coreceptor complex; costimulation; adhesion
CD86	Monocytes, activated B cells	B7-2; ligand for CD28 and CTLA-4; T-cell interaction with antigen-presenting cells; costimulation
CD87	Granulocytes; monocytes/macrophages, activated T cells	Urokinase plasminogen activator receptor
CD88	Granulocytes, macrophages, mast cells	Complement component fragment C5a receptor
CD89	Monocytes/macrophages, granulocytes, B-cell and T-cell subsets	FcαR (IgA receptor)
CD91	Monocytes	α_2-macroglobulin receptor
CD94	NK cells, T-cell subset	Inhibits killing
CD95	Broad distribution	Fas or APO-1; induces apoptosis after being bound by Fas ligand
CD97	Activated B and T cells, monocytes, PMN	Activation antigen
CD102	Resting lymphocytes, monocytes, endothelial cells	ICAM-2; binds LFA-1 (CD11a/CD18); adhesion; T-cell costimulation
CD103	Intraepithelial lymphocytes, T-cell subset	αE integrin; T-cell development and costimulation
CD104	Epithelial cells, Schwann cells	β_4-integrin; epidermal adhesion to basement membrane
CD105	Endothelial cells, bone marrow cell subset, activated macrophages	Endoglin; adhesion
CD106	Endothelial cells	VCAM-1; ligand for VLA-4; lymphocyte adhesion; embryonic development
CD107a,b	Epithelial cells, subsets of monocytes, granulocytes, and lymphocytes	LAMP-1 and LAMP-2; adhesion
CD110	Hematopoietic stem cells, megakaryocytes, platelets	Thrombopoietin receptor; megakaryocyte proliferation and differentiation
CD114	Granulocytes	G-CSF receptor; regulates granulopoiesis
CD115	Monocytes/macrophages	M-CSF receptor; cell differentiation
CD116	Monocytes, neutrophils, eosinophils	GM-CSF a chain receptor; cell differentiation
CD117	Hematopoietic progenitors, mast cells	c-*kit*; stem cell factor (SCF) receptor; hematopoietic cell differentiation
CD118	Broad distribution	Type 1 interferon (interferon-α/β) receptor
CD119	Broad distribution	Interferon-γ receptor
CD120a	Hematopoietic cells, nonhematopoietic cells, myeloid cells	TNF receptor-type I signal transduction; apoptosis
CD120b	Hematopoietic cells, nonhematopoietic cells, myeloid cells	TNF receptor-type II; signal transduction; apoptosis
CD121a	Thymocytes, T-cell subset, fibroblasts, epithelial cells, and brain cells	IL-1 receptor-type I; signal transduction
CD121b	T-cell subset, myeloid cell subsets	IL-1 receptor-type II
CD122	NK cells, T-cell and B-cell subset	IL-2 and IL-15 receptor β chain; signal transduction; regulation of lymphocyte development, differentiation, activation, and proliferation
CD123	Bone marrow stem cells, granulocytes, monocytes, megakaryocytes	IL-3 receptor α chain; cell development and differentiation
CD124	Mature B cells and T cells, hematopoietic precursor cells	IL-4 receptor; signal transduction; lymphocyte development, activation, differentiation, and proliferation
CD125	Eosinophils, basophils, B-cell subset	IL-5 receptor; eosinophil and B-cell growth and differentiation
CD126	Activated B cells, plasma cells, T cells, granulocytes, monocytes/macrophages; also expressed on epithelial cells, fibroblasts, hepatocytes, and neural cells	IL-6 receptor α chain; regulation of B-cell and T-cell differentiation and function; hematopoiesis
CD127	Bone marrow lymphoid precursors, pro-B cells, T-cell precursors, T-cell subset, monocytes	IL-7 receptor α chain; signal transduction; B-cell and T-cell proliferation and differentiation
CD128	Neutrophils, basophils, T-cell subset	IL-8 receptor; neutrophil activation and migration
CD129	T cells	IL-9 receptor α chain; T-cell proliferation
CD130	Broad distribution	IL-6 receptor β chain (with CD126); signal transduction
CD131	Lymphocytes, granulocytes, monocytes	IL-3, IL-5, and GM-CSF receptor; common β chain; signal transduction; see CD123 and CD125
CD132	Lymphocytes	Common γ chain of high-affinity receptor for IL-2 (with CD25 and CD122), IL-4 (with CD124), IL-7 (with CD127), IL-9 (with CD129), and IL-15 (with CD122) receptors; signal transduction

Continued

CD Molecule	Predominant Distribution	Identity/Function
CD134	Activated T cells	OX-40 antigen of TNFR superfamily (binds OX-40 ligand); T-cell–B-cell interaction and T-cell costimulation
CD135	Lymphoid and myeloid cell progenitor subsets	Flt3 ligand receptor; development of myeloid and lymphoid progenitors
CD137	Activated T cells	4-1BB; binds 4-1BB ligand and extracellular matrix components; T-cell–B-cell interaction and T-cell costimulation; extracellular adhesion; signal transduction
CD138	B-cell subset, plasma cells, epithelial cells	Syndecan-1; binds interstitial matrix proteins; B cell–matrix interactions
CD140a,b	Endothelial cells	PDGF receptor α and β chain; embryonic development; signal transduction; chemotaxis
CD141	Endothelium	Thrombomodulin (binds thrombin); regulates coagulation
CD142	Endothelium	Tissue factor; binds plasma factors VII/VIIa; hemostasis, coagulation, and angiogenesis
CD143	Endothelium	Angiotensin-converting enzyme (ACE); binds angiotensin 1; regulates blood pressure
CD144	Endothelium	VE-cadherin; cell–cell adhesion; maintenance of endothelium integrity
CD146	Activated T-cell subset	Mel-CAM, adhesion molecule during development
CD150	T-cell and B-cell subsets	Surface lymphocyte activation marker (SLAM); B cell–T cell interaction; costimulation
CD151	Not defined	PETA-3; regulates platelet aggregation and mediator release
CD152	Activated T cells	CTLA-4; binds B7-1 (CD80) and B7-2 (CD86); T-cell costimulation–negative signal
CD153	T cells	CD30 ligand; T-cell activation, differentiation, and regulation
CD154	Activated T cells	CD40 ligand; T-cell costimulation
CD156a	Leukocytes, B cells	Transmembrane glycoprotein; disintegrin and metalloproteinase domain (ADAM) family member; leukocyte adhesion and protease function; infiltration of myelomonocytic cells
CD156b	Broad distribution	TNF-α-converting enzyme (TACE); disintegrin and metalloproteinase domain (ADAM) family member; cleaves TNF and transforming growth factor-α from cell surface, thereby releasing soluble form
CD158	NK cells	Killer immunoglobulin-like receptors (KIR); family of molecules that inhibit NK cytotoxic activity
CD159a	NK cells	NKG2A (killer cell lectin-like receptor)
CD161	NK cells	Natural killer cell receptor-P1; target cell recognition; NK cell activation
CD162	Granulocyte and T-cell subsets	P-selectin glycoprotein ligand-1 (PSGL-1); adhesion
CD166	Activated T cells, B cells	ALCAM; binds CD6; T-cell activation; thymocyte development
CD167a	Epithelial cells	Discoidin domain receptor 1 (DDD1); tyrosine kinase receptor; binds to collagen; cell–cell contact and adhesion
CD178	Activated T cells; various tissue cells	FAS ligand (ligand for CD95); binding to FAS triggers apoptosis
CD179a	Pro-B and pre-B cells	VpreB; forms surrogate light chain with CD179b; early B-cell differentiation
CD179b	Pro-B and pre-B cells	$\lambda 5$; forms surrogate light chain with CD179a; early B-cell differentiation
CD180	B cells	RP105; toll-like receptor family; regulates B-cell recognition and signaling of LPS
CD183	Effector/memory T cells, NK cells, eosinophils	CXCR3 receptor for interferon-inducible chemokines IP10, Mig, and I-TAC; chemotactic migration of effector T cells into areas of inflammation
CD184	Leukocytes; hematopoietic progenitors	CXCR4 receptor for chemokines such as stromal cell-derived factor 1 (SDF-1) (fusin); chemotaxis; HIV-1 coreceptor
CD195	Broad distribution; myeloid cells, lymphocytes, T lymphocytes, neurons, epithelium, endothelium	CCR5 receptor for chemokines such as macrophage inflammatory proteins, MIP-1a and MIP-1b, and RANTES; chemotaxis; HIV-1 coreceptor
CDw197	Lymphoid tissues, B cells, T-cell subset	CCR7 chemokine receptor; chemotaxis; T-cell homing and migration
CD201	Endothelial cells	Protein C receptor; coagulation
CD203c	Mast cells, basophils	Member of the ectonucleotide pyrophosphatase/phosphodiesterase enzymes
CD204	Myeloid cells, monocytes/macrophages	Macrophage scavenger receptor-1 (MSR1); mediates binding, internalization, and processing of various negatively charged macromolecules
CD206	Dendritic cells, macrophages, myeloid cells, endothelial cells	Mannose receptor, C-type 1; binds microorganisms; phagocytosis
CD207	Dendritic cells, Langerhans cells	Langerin; mannose receptor; phagocytosis and internalization of antigen for processing
CD208	Dendritic cells	DC-LAMP
CD209	Dendritic cells	DC-SIGN
CDw210	Broad distribution	I1-10 receptor α and β chain
CD212	T cells, NK cells	IL-12 receptor β_1 chain
CD213a1,a2	Lymphocytes, bronchial epithelial and smooth muscle cells	IL-13 receptor α_1 and α_2 chains
CDw217	Activated T-cell subset	IL-17; cytotoxic T-lymphocyte–associated serine esterase 8; stimulates cell activation; induces osteoclast differentiation factor (ODF)
CD220	Broad distribution	Insulin receptor; stimulates glucose uptake
CD molecule	Predominant distribution	Identity/function
CD221	Broad distribution	Insulin-like growth factor 1 receptor; cell signaling; activation, and differentiation
CD222	Broad distribution	Mannose-6-phosphate receptor; insulin-like growth factor 2 receptor
CD226	NK cells, platelets, monocytes, T-cell subset	Platelet and T-cell activation antigen 1 (PTA1); adhesion
CD233–241	Erythrocytes	Various erythrocyte membrane antigens, including blood group–associated glycoproteins

CD Molecule	Predominant Distribution	Identity/Function
CD242	Erythrocytes	ICAM-4
CD246	T cells	TCR or CD3 ζ chain; associated with TCR and CD3; couples TCR recognition with T-cell signaling
CD247	T cells	T cells ζ chain of the TcR
CD252	Activated B cells	OX40 ligand
CD253	Activated T cells	TRAIL, death receptor
CD254	Activated T cells, LN and BM stroma	RANK ligand
CD256	Monocytes, macrophages	APRIL, binds TACI and BCMA
CD257	Activated monocytes	BLyS, BAFF, binds TACI, BCMA, BAFFR, induces B-cell proliferation
CD261	Activated T cells, peripheral leukocytes	TRAIL-R2, DR5, death receptor
CD262	Peripheral lymphocytes	TRAIL-R1, DR4, death receptor
CD263	Peripheral lymphocytes	TRAIL-R3, DcR1, death receptor
CD264	Peripheral lymphocytes	TRAIL-R4, DcR2, death receptor
CD265	Broad distribution	RANK
CD267	B cells, activated T cells	TACI
CD268	B cells	BAFFR, binds BLys, mature B-cell survival
CD269	Mature B cells	BCMA, binds APRIL and BAFF, B-cell survival and proliferation
CD275	B cells, dendritic cells, monocytes	ICOSL, costimulation, cytokine production
CD278	Activated T cells	ICOS, T-cell costimulation

ADCC, antibody-dependent cellular cytotoxicity; *ALCAM,* activated leukocyte cell adhesion molecule; *APRIL,* a proliferation-inducing ligand; *BCMA,* B-cell maturation antigen; *BCR,* B-cell receptor for antigen; *DC,* dendritic cell; *CTLA,* cytotoxic T lymphocyte antigen; *EBV,* Epstein-Barr virus; *ELAM,* endothelial leukocyte adhesion molecule; *G-CSF,* granulocyte–colony-stimulating factor; *GM-CSF,* granulocyte macrophage–colony-stimulating factor; *GPI,* glycosyl-phosphatidylinositol; *HIV,* human immunodeficiency virus; *ICAM,* intercellular adhesion molecule; *ICOS,* inducible T-cell costimulator; *Ig,* immunoglobulin; IL, interleukin; *LAM,* leukocyte adhesion molecule; *LAMP,* latent membrane protein; *LDL,* low-density lipoproteins; *LECAM,* lymphocyte endothelial cell adhesion molecule; *LFA,* lymphocyte function antigen; *LPB,* lipopolysaccharide binding protein; *LPS,* lipopolysaccharide; *MAdCAM-1,* mucosal addressin cell adhesion molecule-1; *M-CSF,* macrophage colony-stimulating factor; *MHC,* major histocompatibility complex; *NK cells,* natural killer cells; *PDGF,* platelet-derived growth factor; *PECAM,* platelet endothelial cell adhesion molecule; *PETA,* platelet-endothelial cell tetraspan antigen; *PMN,* polymorphonuclear neutrophil; *SIGN,* specific intercellular adhesion molecule–grabbing nonintegrin; *TACI,* transmembrane activator and CAML interactor; *TCR,* T-cell receptor for antigen; *TNF,* tumor necrosis factor; *TNFR,* tumor necrosis factor receptor; *TRAIL,* TNF-related apoptosis inducing ligand; *VCAM,* vascular cellular adhesion molecule; *VLA,* very late antigen.

This list was adapted from the results of the Eighth International Workshop on Human Leukocyte Differentiation Antigens (HLDA8) held in Adelaide, Australia, in December 2004 (Proceedings of the 8th International Workshop on Human Leukocyte Differentiation Antigens. December 12–16, 2004. Adelaide, Australia. Cell Immunol 2005;236[1–2]:1–187). Engel P, Boumsell L, Balderas R, et al. CD nomenclature 2015: human leukocyte differentiation antigen workshops as a driving force in immunology. J Immunol 2015;195:4555–4563.

APPENDIX 2

Laboratory Reference Values

Thomas A. Fleisher

Immunoglobulin Levels (Age-Related Reference Ranges; see Chapter 93)

Age of Healthy Donors	IgG g/L	$\mathrm{IgG_1}$ g/L	$\mathrm{IgG_2}$ g/L	$\mathrm{IgG_3}$ g/L	$\mathrm{IgG_4}$ g/L	IgA g/L	$\mathrm{IgA_1}$ g/L	$\mathrm{IgA_2}$ g/L	IgM g/L

Immunoglobulin (Ig) levels were assessed in serum by nephelometry, and data were statistically analyzed for the mid-95% confidence interval. For total IgG and IgG subclass quantitation, data from 156 pediatric and 92 adult donors were used; for total IgA quantitation, data from 201 pediatric and 99 adult donors were used; for IgA subclasses, data from 119 pediatric and 99 adult donors were used; and for IgM quantitation, data from 212 pediatric and 401 adults were used at Mayo Medical Laboratories.

Total Serum IgE (IU/mL)

Age	Gender	Geometric Mean	Upper 95% Confidence Limit
6–14 years	M	42.7	527
	F	43.3	344
15–24 years	M	33.6	447
	F	18.6	262
25–34 years	M	16.8	275
	F	16.6	216
35–44 years	M	21.7	242
	F	19.3	206
45–54 years	M	19.2	254
	F	13.3	177
55–64 years	M	21.3	354
	F	11.7	148
65–74 years	M	21.2	248
	F	11.5	122
>75 years	M	18.4	219
	F	9.2	124
6–75 years	all M	22.9	317
	all F	14.7	189

Data were generated using individuals with negative skin prick tests (i.e., house dust mite, Bermuda grass, tree mix, weed mix, mold mix).
From Barbee RA, Halonen M, Lebowitz M, Burrows B. Distribution of IgE in a community population sample: correlations with age, sex, and allergen skin test reactivity. J Allergy Clin Immunol 1981;68(2):106–11, with permission.

Lymphocyte Immunophenotype: Adult Reference Range (95% Confidence Interval)

Surface Antigens	Percent Positive	Cells/mm^3
T Cells		
CD3	60–83.5%	714–2266
CD5	60–83.5%	723–2276
CD2	77.5–94%	817–2496
CD7	74–96.0%	775–2536
CD3/CD4	32–62%	359–1565
CD3/CD8	11–35%	178–853
CD4/CD45RO	10–44%	173–916
CD4/CD45RA	4–21%	55–593
CD8/CD45RO	1.5–11.5%	36–273
CD8/CD45RA	2.5–20.5%	44–405
CD3/CD8/CD28	9.5–26%	126–600
CD8/CD57	≤30.0%	≤521
CD3/HLA-DR	≤19.5%	≤450
CD3/CD25	11–40%	155–905
B Cells		
CD20	3–19%	59–329
CD19	3–19%	61–321
CD20/CD5	0.5–9.5%	14–159
CD20/CD23	1–14%	27–229
CD20/CD27	1–3.5%	12–68
NK Cells		
$\mathrm{CD3^-/CD16^+/CD56^+}$	6–35%	126–729
Lymphocytes	17–41	1173–2640

Data generated in the Flow Cytometry Section, Immunology Service, DLM, CC, NIH, Bethesda, MD. The 95% confidence interval for the WBC is 4300–9200/mm^3.
